The prognosis depends partly upon the associated disease and partly upon the relative rates of venous occlusion and the development of a collateral circulation The mortality rate is high Death usually occurs in a few months but survival for many decades is possible In one personally observed case the thrombosis followed an acute tonsillitis this patient was still alive after six years although he suffered from extreme vertigo when his position was changed suddenly We have seen tuberculous endophlebitis of the superior vena cava with occlusion unfold its picture in a matter of weeks sometimes there is a marked change of personality before death

In recent years surgery has provided great relief to patients with this syndrome The azygos vein has been grafted into the right atrium or with the aid of arterial grafts it has been anastomosed to an innominate vein and patent parts of the superior vena cava

OCCLUSION OF THE INFERIOR VENA CAVA

A thrombosis or thrombophlebitis in the course of an infectious disease occasionally causes an occlusion of the inferior vena cava More often this event is due to a thrombus propagated from another vein Most common in our experience is occlusion of the inferior vena cava by a renal new growth in which a large mass of neoplastic tissue ascends the inferior vena cava

When occlusion of the inferior vena cava complicates the terminal phase of some other disease the clinical picture need not be modified When symptoms develop at all they consist mainly of leg edema and edema of the back without ascites The urinary output may diminish Subsequently an extensive collateral circulation may develop in which the superficial veins of the abdominal wall participate However we have observed collateral circulations in which the deep veins of the abdominal wall alone acted vicariously for the occluded vena cava and the diagnosis was impossible since no collateral circulation was visible externally

Among the measures for symptomatic relief repeated venesection may possess great value It may not prolong life but it may relieve many annoying symptoms for 48 hours or more

From the standpoint of differential diagnosis the principal source of confusion has been to mistake occlusion of the inferior vena cava for Baumgarten's

syndrome of the paraumbilical veins In both a remarkable caput medusae may be present but otherwise there is little similarity The outstanding signs of Baumgarten s syndrome apart from the caput medusae and thrill is splenomegaly and at least in many cases the recurrent ascites moreover Baumgarten s syndrome in our experience is seen in young individuals of the asthenic habitus who frequently lack secondary sex characteristics

Suppurative pylephlebitis and its relationship to appendicitis and to liver abscess endophlebitis syphilitica of the hepatic veins (Chiari s disease) splenic vein thrombosis and its association with the Banti syndrome various types of portal vein thrombosis and particularly the relatively common form observed in connection with cirrhosis of the liver as well as many other diseases of the veins belong to the domain of Internal Medicine and are not discussed in this volume

Chapter 31

Therapy

General Remarks

In this chapter some measures available for the treatment of cardiac diseases are reviewed. A large number of therapeutic procedures for special conditions have already been discussed in the preceding individual chapters. The agents serving especially for the management of cardiac failure will find consideration in the discussion which follows.

Cardiac failure and decompensation should not be treated exclusively with drugs. Rest and appropriate diet alone will restore compensation in many patients.

The method of treatment so popular in the past, consisting of complete digitalization and then dismissal of the patient until cardiac failure reappeared, has been properly abandoned. Such treatment can be compared to leaving a non-swimmer under water and lifting his head out of the water now and then to prevent complete asphyxia. The patient must be under continuous control; his activities must be planned and discussed in detail with him. Compensation must be maintained by the mode of living as well as by continuous administration of drugs.

When decompensation develops, an endeavor should be made to determine its cause. Knowledge of the precipitating factor helps greatly in treatment. Often the appearance of an arrhythmia, particularly atrial fibrillation, of an infection with hemolytic streptococci, pulmonary embolism, extra physical strain or undernutrition will precipitate cardiac failure. In all these instances it is possible for the situation to improve after the disappearance or elimination of the precipitating factor. After they have recovered from cardiac failure, these patients may have an efficient and fully compensated circulation for years.

Decompensation must be considered much more grave, however, if it develops from failure of a markedly dilated heart or a steadily progressive process such as coronary sclerosis. Under these circumstances there is not much prospect that the state of the patient will remain satisfactory without continuous treatment. But even in the latter instance decided improvement may occur if, in the case of an earlier infarction, collateral circulation develops and strong scars are formed in the myocardium. Therefore, even the symptoms and signs of advanced cardiac failure in coronary sclerosis should never lead to an absolutely poor prognosis.

Psychotherapy has considerable importance in the management of decompensated patients and should not be neglected. All encouraging features should

be stressed such terms as cardiac failure should be avoided in discussion with the patient The term congestion is less alarming The importance of preventing mental strain and nervous tension in patients with hypertension or coronary thrombosis was mentioned in the respective chapters

The removal of visible edema dyspnea or tachycardia is not the ultimate objective of therapy Many weeks of treatment sometimes are needed until the heart acquires sufficient reserve and the patient is in an optimal condition The disappearance of dyspnea or edema does not constitute the maximal benefit from treatment

A discussion of the sexual life of the patient ought not to be omitted because of a false sense of prudery Actually patients are often thankful that they were anticipated in this question which they may have hesitated to raise In cases of coronary disease many deaths during sexual intercourse could have been prevented if the patient had been told to take nitroglycerin before the act

Greatest attention should be devoted to the treatment and prevention of all infections It was shown in the chapter on myocarditis how often the heart muscle is involved in various infections Patients with advanced valvular lesions or severe hypertension remain compensated for years as long as the heart muscle is normal but the slightest impairment of the myocardium may lead to cardiac failure It is readily conceded that dental granuloma gingivitis and dental abscesses do not play the role ascribed them by some advocates of the doctrine of oral sepsis Nevertheless foci of this kind possess great and often underestimated significance in many cases

Medicine possesses no satisfactory test for estimating the functional capacity of the heart and none for the early diagnosis of decompensation All the innumerable tests described such as registration of the heart rate and the respiratory rate the blood pressure at rest and after measured work and all the recommended combinations of these tests have little value The least exertion may increase the pulse rate and blood pressure more in the otherwise healthy neurotic individual than in a decompensated patient A careful history and exact examination furnish much more information on the state of the circulation of the patient than any of the functional tests now available

DIGITALIS

No other drug employed in medicine has created a literature as voluminous as that of digitalis Numerous monographs and innumerable experimental and clinical papers have digitalis as their subject While much research has been done particularly in recent years on digitalis glycosides and on purification of the drug the clinical rules laid down by Withering still hold and have been little improved This does not reflect adversely on the scientific zeal of workers in all countries but merely proves how unusual the experience the excellent powers of observation and the remarkable descriptions of Withering

Chemistry

Among the many plants of the digitalis group the leaves of digitalis purpurea and of digitalis lanata are used almost exclusively at present as the source of digitalis preparations Digitalis lanata is a species of foxglove that has the advantages of easy cultivation and a large content of active glycosides

The digitalis glycosides are composed of an aglucone (genin) fraction and a sugar fraction The latter is important for the solubility of the glycoside and enables it to penetrate the cells The aglucone fraction has a phenanthrene structure similar to that of the sex hormones (sterols) and desoxycorticosterone and exerts the specific cardiac effect

The three glycosides isolated from the leaves of digitalis purpurea — digitoxin gitoxin and gitalin — are known to have precursors they are not genuine glycosides (Stoll) These have still not been isolated

From digitalis lanata three products digilanid A digilanid B and digilanid C have been isolated from these digitoxin gitoxin and digoxin are derived

Digitalis contains many other substances among them the saponins which promote absorption from the gastrointestinal tract

The isolation of pure crystalline products digitoxin from digitalis prupurea (digitaline Nativelle isolated as early as 1869) digoxin (isolated by Smith in 1930) and cedilanid from digitalis lanata makes possible the administration of pure products of known strength

Pharmacology

Action of the Heart Muscle Digitalis glycosides increase the contractility of the myocardium This is seen even in isolated muscle strips and may also be observed microscopically in fibers from the specific tissue Systole is strengthened and is more complete so that the heart empties better The heart muscle is enabled to overcome greater resistence and its absolute power is increased The minute volume may be doubled There also are some effects on the diastolic phase although they are not very pronounced in the mammalian heart The speed of relaxation is increased but diastolic size is not reduced The increased velocity of the contraction shortens the duration of systole and the refractory phase (Junkmann) The pump works quicker stronger and the piston of the pump goes deeper than before digitalization

The action of digitalis on actomyosin and adenosine triphosphate is not clear It is possible that the diminished amount of ATP (Wollenberger) in the heart of patients with thiamine deficiency or hyperthyroidism explains the poor effect of digitalis in these conditions Digitalis increases the glycogen content of the heart muscle and diminishes the amount of lactic acid According to Pothlin et al digitalis interferes with energy utilization and not with energy production Bing et al found that strophanthin does not affect oxygen consumption of the failing heart which remains normal According to Proctor et al digitalis influences the enzyme systems that regulate the level of adenosine triphosphate

In patients with heart failure digitalis leads to disappearance of congestion diminution of residual blood fall of atrial pressure lower venous pressure better nutrition of the tissues and finally to an increase of the cardiac reserve power The peripheral blood depots open partly due to the disappearance of edema and partly due to widening of the peripheral vessels by other mechanisms All these actions begin soon and bring about a remarkable improvement It is claimed that digitalis is ineffective in high output failure This is true in our opinion only if the causative factor (pulmonary pathology arteriovenous fistula etc) persists in great intensity

Action on the Vagus Digitalis glycosides increase the vagal inhibition of the heart This effect is not of central origin it has been explained by increased sensitivity of the receptors in the carotid sinus (Heymans et al) or by sensitization of the heart muscle to the (normal) vagal tone (Abdon and Nielson)

This heightening of vagal inhibition is beneficial It may slow the heart particularly in cases of atrial fibrillation where it slows the ventricles by inhibiting the atrioventricular conduction The contractility of the ventricles is not impaired by this vagal action since — as was pointed out before — there are no vagus fibers and therefore no direct vagal effects on the mammalian ventricle

The conduction of a stimulus over the heart is directly impaired by large doses of digitalis This effect is observed even in isolated muscle strips

Action on Blood Vessels Much has been written about the vascular effect of digitalis glycosides A general vasoconstriction particularly in the gastro intestinal tract seems to take place under certain conditions but not with doses comparable to those used in therapeutics This effect is also counteracted by the improved peripheral blood supply the result of the stronger and shortened systole The special situation of the coronary arteries will be discussed later

There is no proof of a direct diuretic effect on the kidneys Any increase in urinary output is the indirect consequence of the improvement of circulation

Action on the Normal Heart It is often maintained that digitalis does not affect the normal heart but this statement is certainly untrue It must be expected that the efficiency of the systolic contraction will not be remarkably increased if the heart works under normal conditions The minute volume cannot increase as long as the inflow of blood to the heart remains the same If toxic doses of digitalis are given to healthy individuals the minute volume falls a finding that could be anticipated in view of the toxic effects of large doses of digitalis on the heart muscle According to some authors the diminished output is due to peripheral factors (Dock and Tainter)

Fixation and Cumulation Digitalis is fixed in the heart (Hatcher) It is still present 28 days after administration of one large dose It has been estimated that the heart loses daily 3 to 7 per cent of the cumulative amount of digitoxin The binding of scilla and strophanthin is slight Friedman et al found that the renal excretion of digitoxin lasted 24 days It is significant that elderly patients excrete much smaller amounts

The digitalis glycosides cumulate Even very small doses may suddenly exert toxic effects when repeated often over a sufficient length of time Originally cumulation was explained by simple addition until it was shown that large sublethal doses of digitalis cause necrosis of the myocardial fibers This necrosis was seen first in 1904 but was completely forgotten until it was rediscovered in recent times It is not yet decided whether the necrosis is caused by a direct action of the digitalis on the myocardium or whether it is due to ischemia Digitalis in sublethal doses also causes hyaline necrosis in the aorta and in the walls of the renal and coronary arteries Degenerative changes have also been seen in the brain The necrosis and hyaline degeneration in the myocardium is situated around the papillary muscles in particular it is followed by secondary leukocytic infiltration We may assume that smaller doses of digitalis alter the myocardial cell without leading to histologic changes It is probable that the cumulation is due to the increased sensitivity of the myocardium altered by small doses of digitalis to additional doses

The heart was supposed to store more digitalis than any other organ However recent investigations with the embryonic duck heart as test object (Friedman et al) speak against this predilection The authors found the greatest concentration in the liver and kidneys It is interesting to note that the tissues of the rabbit (examined by Friedman s technique) do not retain digitalis as compared to the tissues of other animals Digitalis is fixed by the cat heart but not by the rat heart and even the cat heart does not fix more than other organs of this animal This should be a warning against drawing conclusions from one species to another

The maximum capacity for destroying digitalis is according to Friedman et al 50 micrograms daily This amount is the same whether 0 1 or 0 2 mg of digitoxin are given

Most of the digitalis administered is excreted by the urine (80 per cent) and feces in an inactive form Only traces of active substances are excreted

Using radioactive digitoxin Okita et al found minute amounts in the heart after 40 days

Electrocardiogram The digitalis glycosides cause visible effects in the electrocardiogram The shortening of systole can be measured in the electrocardiogram and may amount to 41 per cent (Berliner) Within a few hours a single large dose may depress the PS T segments and lower the T waves These changes may persist for more than three weeks after discontinuation of treatment (figure 114) Extrasystoles will be discussed later Digitalis also causes atrioventricular conduction disturbances In some hearts with a damaged myocardium they appear following small doses

In figure 115a a prolonged P P interval exists The tracing was obtained from a 56 year old patient with hypertension who had received 0 3 Gm of digitalis daily for 18 days in the form of tablets of powdered leaves The P P interval measured 0 32 second In lead I the third atrial stimulus is not conducted to the

ventricle the following conduction is shorter due to partial recovery (Wenckebach's period) The RS-T segments and T waves are displaced in a direction opposite to the main deflection, a typical digitalis effect Figure 115b was

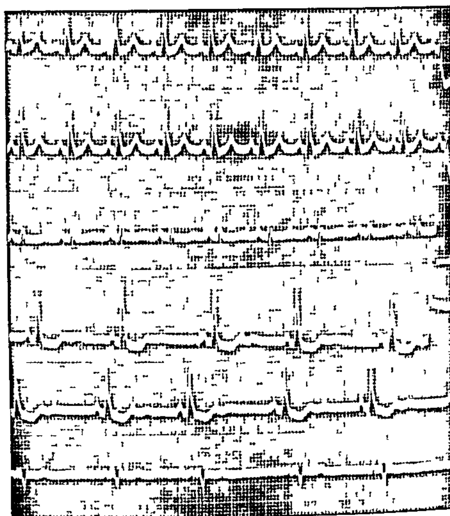

FIG 114 The upper three strips represent the three standard leads before, the lower 3 strips after digitalis therapy Note the change of rate and the depression of the RS-T segments with lowering of the T waves U waves appear this is common and may be explained by the diminished content of potassium in the heart muscle

taken from the same patient 17 days after digitalis had been discontinued The digitalis effects (conduction disturbances shortening of systole and RS-T changes) have disappeared

Standardization Methods for standardization of digitalis according to the amount necessary to cause standstill of the frog or cat heart in a given time

under certain experimental procedures are in wide use One should not forget however that preparations having the same strength experimentally (containing the same number of cat units) may have a quite different activity in men Even cat units cannot be compared with each other because of different methods used Likewise they cannot be compared to frog units since preparations having the same number of frog units may have different toxicity when tested in cats Therefore the labels indicating standardization of a preparation on frogs or cats may be somewhat misleading They often give a false sense of

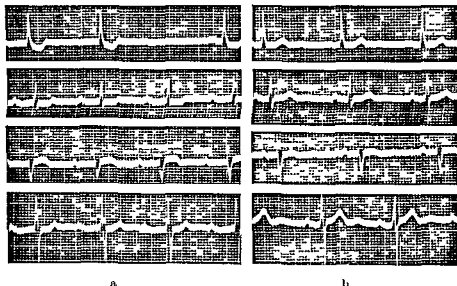

FIG 115 Atrioventricular block and deformation of the RS T segments and T waves caused by digitalis (a) Only left axis deviation remains 17 days after digitalis was discontinued (b)

security in dosage In a similar way standardization in man which has often been tried encounters great difficulties

Many preparations particularly tincture of digitalis deteriorate rapidly The pure glycosides do not require bioassay

Indications

Scientific evidence and reasoning often only superficially accurate cannot yet be conceded the final argument for or against the administration of digitalis in a special case The dose and mode of treatment must be determined by the real benefit the patient derives from it A long life is too short to learn enough about this wonderful drug (Wenckebach)

These sentences written by a great cardiologist illustrate clearly the superiority of practical experience over theoretical knowledge in digitalis treatment

Digitalis therapy is a great art that cannot be learned from books Only the inexperienced take it lightly Lives may be saved or astonishing improvement may be accomplished by a slight increase in dosage the addition or decrease of one tablet of 0 1 Gm of digitalis per day may change the whole picture

An exact knowledge of the indications and contraindications is the necessary basis for any therapeutic program with digitalis

There are two main indications for the treatment (1) evidence of cardiac failure (2) arrhythmias particularly atrial fibrillation with too rapid a ventricular rate

Cardiac Failure In the presence of rhythmic cardiac action evidence of myocardial failure is the only indication for digitalis Cardiac failure is evidenced not only by edema dyspnea and engorgement of the liver but also by Cheyne Stokes respiration nocturnal cough hydrothorax and pulmonary congestion Digitalization should not be postponed until cardiac weakness has fully developed The drug should be given at the first sign of myocardial failure

It has been stated that digitalis never helps patients with rhythmic cardiac action unless hypertrophy of the heart exists in combination with dilatation (Edens) Although no proof can be cited to support this statement there is some truth in it In concentric hypertrophy alone digitalis is not indicated and no help can be expected from it since the heart is not decompensated and no failure exists In patients with pure dilatation as in a case of toxic myocardial damage or following unusual strain digitalis is useless Digitalis is also useless in the myocardial necrosis of diphtheria and coronary sclerosis and in the myocardial damage of rheumatic fever Only if the basic condition or another disease in these cases (hypertension chronic coronary artery disease) has already led to hypertrophy and dilatation does the drug improve the condition of the patient

Digitalis is of course useless in congestive failure caused by pericarditis or cardiac tamponade Only in slowly developing myocardial failure as it actually happens in the majority of decompensated cardiac patients in whom hypertrophy and dilatation of some part are combined is digitalis useful

Digitalis is administered to these cases primarily for its positive inotropic effect that is to improve the contractile power of the heart muscle

In the presence of rhythmic cardiac action slowing of an accelerated cardiac rate (sinus tachycardia) by digitalis is often impossible If the tachycardia is caused by decompensation (Bainbridge reflex) it may disappear during digitalization (figure 114) but in many cases it persists unless toxic doses are used Thus in mitral stenosis with regular sinus rhythm and sinus tachycardia the rate remains rapid even if large doses of digitalis are administered In those patients who also exhibit marked pulmonary congestion digitalis is of little or no value because it does not help overcome the valvular defect and neither ventricle is incompetent Sometimes a tachycardia has a compensatory effect to maintain cardiac output as pointed out before

An increase of rate alone need not be the occasion for inaugurating digitalis therapy since cardiac acceleration occurs in the absence of decompensation

Thus considerable tachycardia may be encountered in a cardiac neurosis in hyperthyroidism in patients with aortic regurgitation in endo and myo carditis and other conditions without coexisting decompensation Often an entirely superfluous digitalis therapy is initiated in these patients It is on the other hand well known that digitalis often restores compensation without slowing the heart

Occasionally digitalis is withheld from decompensated patients even when they suffer nightly from attacks of paroxysmal dyspnea simply because the cardiac rate is slow One may encounter severely decompensated patients in whom the cardiac rate does not exceed 60 to 70 beats per minute Not rarely this happens to patients with coronary sclerosis in whom this bradycardiac decompensation may be due to abnormal nutrition of the sinus node It occurs in aortic stenosis The hesitancy to give digitalis in these patients is not justified The heart rate in these patients does not become slower during digitalis treatment and digitalization will cause marked improvement

Arrhythmias The second indication for digitalis therapy is seen even in the absence of cardiac failure it is represented by cases of atrial fibrillation and a rapid ventricular rate Here as pointed out before engorgement of the liver venous congestion and edema appear early when the ventricular rate is high In these cases impairment of conductivity by the direct action of digitalis on the specific tissue and via the vagus slows the ventricular rate to values between 70 and 80 beats per minute As soon as this level is reached the circulation is in an optimal condition Since with rare exceptions slowing occurs regularly with the employment of relatively small doses these patients react exceedingly well to digitalis Only a slight impairment of conductivity is necessary to prevent the majority of the weak stimuli originating in the fibrillating atrium from reaching the ventricle In rare cases atrial fibrillation may disappear during digitalis treatment even rarer are patients in whom the onset of fibrillation coincides with the treatment The special method of treating atrial flutter with digitalis has been discussed earlier

Other arrhythmias such as atrial extrasystoles and paroxysmal tachycardias are also abolished by digitalis but they respond better to other drugs e g quinidine

Other Indications Apart from the group of patients presenting cardiac failure and those with atrial fibrillation and flutter there are only rare indications for digitalis One is mentioned below in connection with heart block

The administration of digitalis in infectious diseases or preoperatively in order to strengthen the heart has been properly abandoned In these conditions peripheral circulatory failure rather than cardiac failure develops occasionally and digitalis is useless The administration of digitalis in pneumonia in the pre antibiotic era was abandoned after it was shown that there was no proof that routine administration of digitalis in these cases lowers the mortality It has also been recognized for a long time that cardiac weakness is not responsible for shock in this condition digitalis is therefore often without value

Contraindications

The contraindications to digitalis since they are so few may be summarized briefly Our claim that such contraindications are practically nonexistent is based on the fact that whenever the administration of digitalis is necessary it *must* be carried out since there is no substitute If cardiac failure is present or if the ventricular rate is too high in atrial fibrillation therapeutic success is not obtained without digitalis and the condition of the patient steadily deteriorates unless it is given Naturally there are patients in whom large doses of digitalis must be avoided but no contraindication to digitalis is admitted Allergy or intoxication signs mentioned below occasionally prevent continuation of treatment

For obvious reasons digitalis will not help in congestion of the liver and veins in pericardial diseases or cardiac tamponade nor will it abolish dyspnea due to pulmonary disease Even in patients with mitral stenosis and pulmonary congestion with sinus rhythm digitalis is not indicated and is useless

Since some older textbooks enumerate an entire series of contraindications they must receive some mention in this section

Paroxysmal Ventricular Tachycardia This disturbance — contrary to prevailing opinion — is a contraindication to digitalis therapy only when it appears during the administration of digitalis and is elicited by it Attacks of ventricular paroxysmal tachycardia not induced by digitalis are no contraindication and in fact respond favorably to it Thus we saw success in ventricular tachycardias following acute myocardial infarction even when quinidine was ineffective Scherf and Kisch observed a patient with attacks of ventricular tachycardia with alternating forms of ventricular complexes that always disappeared when digitalis was given

High Blood Pressure A warning was issued against digitalis therapy in the presence of an elevated blood pressure owing to the alleged danger of a further rise during the course of treatment The improved contractility and the shortening of the systole actually should lead to an increase of systolic blood pressure However so many regulating factors influence the level of the systolic blood pressure that at the bedside its height can always be disregarded in the question whether digitalis is necessary Often in decompensated hypertensive cardiac patients the blood pressure even falls during the course of the treatment of hypertension if decompensation was the cause of the hypertension (stasis hypertension) In other cases the blood pressure increases during digitalization But in these instances hypertension was present for a long time during the period of failure the blood pressure dropped but rose once again as digitalis therapy improved ventricular contractility

Embolism Patients who recently experienced an embolism in the lesser or greater circulation were often considered unsuitable for digitalis because of the fear that more powerful contractions of the heart induced by the drug might lead to the release of more thrombi and cause further embolism Any increase of

cardiac action due to a rapid movement or unavoidable excitement naturally offers the same danger Furthermore in these cases as in all others digitalis is given only when indicated therefore it must be administered since there is no drug with a different mode of action that can replace it

Coronary Disease Many physicians withhold digitalis from patients with angina pectoris and myocardial infarction In patients with anginal pain the detrimental effect due to narrowing of the coronary arteries is considered dangerous while in myocardial infarction rupture of the heart the result of more powerful contractions after digitalis is considered possible

Despite a tremendous amount of experimental work concerning the effect of digitalis (and strophanthin) on the coronary blood flow no decisive results have been obtained This is largely due to the fact that the coronary blood flow during digitalis therapy is influenced by factors which in many respects act oppositely The increase of cardiac contractility with shortening of the systole and the change of the heart rate may improve coronary blood flow while the increased vagus tone may diminish it A direct action of digitalis on the coronary vessels can only be studied in experiments on excised isolated vessels According to some investigators toxic doses narrow the coronary vessels No effect or only negligible reduction of blood flow is reported by others

Large doses of digitalis were given to 15 patients with angina pectoris and a positive exercise test i e marked changes in the electrocardiogram on exertion and in only one case did the complaints slightly increase in this single instance the alterations in the electrocardiogram became more pronounced on exertion after digitalis therapy (Hauser and Scherf)

Clinical experience shows that digitalis should be given if indicated to patients with angina pectoris due to coronary stenosis or patients with myocardial infarction

In cases of angina pectoris on effort the attacks occasionally disappear during the period of decompensation and reappear once compensation is restored This fact well known for many years has been questioned recently We have observed it repeatedly particularly in cases of aortitis and angina pectoris due to coronary stenosis The physician faces a dilemma and must choose between the Scylla of angina pectoris and the Charybdis of cardiac failure The disappearance of angina on effort in decompensation may be accounted for by the diminished activity of the patient due to dyspnea, edema and so forth But the fact that anginal pain at rest may also disappear has not as yet been satisfactorily explained

In coronary thrombosis with myocardial infarction the appearance of pulmonary congestion alone especially in the first few days is no indication for digitalis One will often succeed in preventing pulmonary edema and abolishing dyspnea by means of small doses of morphine and the congestion will disappear within a few days If however the signs of congestion increase despite morphine or if gallop rhythm and other signs of myocardial damage appear digitalis must be given The effect here often is as miraculous as in other cases Digitalis may

be particularly necessary in patients with a second or third attack of myocardial infarction or patients with chronic hypertension who develop myocardial infarction

Heart Block Cases of heart block (atrioventricular block) are often cited as unsuitable for digitalis therapy because of the danger of further cardiac slowing If complete atrioventricular block is present this fear is groundless since digitalis does not reduce the automatism of the ventricular centers but rather augments it if proper dosage is used Accordingly patients with heart block and a ventricular rate even as low as 20—30 may be digitalized without danger In patients with an incomplete heart block digitalis therapy may lead to a complete interruption of the atrioventricular conduction This event represents a lesser evil than non digitalization of a failing heart In fact digitalis is prescribed in atrial fibrillation for the purpose of impairing atrioventricular conduction and producing heart block Therefore cautious administration of digitalis in cases of heart block is permissible and even indicated when continuous change from partial to complete A V block causes Stokes Adams attacks

Signs of Intoxication and Side Effects of Digitalis Treatment

While true contraindications to digitalis treatment do not exist in some cases the administration of the drug must be interrupted even if its continuation seems indicated Interestingly enough many of these signs of intoxication and side effects of digitalis therapy were known to Withering

Allergy The administration of digitalis is sometimes impossible because of allergy to the drug Instances of scarlatiniform rashes urticaria asthma pruritus edema of the face and fever caused by digitalis have been described Rarely we have also seen skin rashes appear during the administration of strophanthin

Nausea and Vomiting Digitalis vomiting is not the result of direct irritation of the gastric muscosa since vomiting occurs on parenteral administration nor is it due to irritation of the vomiting center Some investigators considered reflexes emerging from the heart and running predominantly over the vagus responsible while others assumed that reflexes from the liver or other abdominal viscera cause it Vomiting has been observed however even after extensive severance of connections between the heart and the abdominal organs from the central nervous system Digitalis is said to have a central emetic effect which summates the effects caused by stimulation of peripheral reflexes outside the intestine (Borison) The oral administration of galenic preparations may cause direct irritation of the stomach by virtue of the saponins and other ballast substances

The vomiting often comes in waves with periods of relative wellbeing between them

If vomiting occurs during the course of digitalis treatment one possibility should always be considered namely that the doses administered are too small

to control the failure and the vomiting is due to hepatic enlargement and congestion This type of vomiting naturally vanishes if therapy is continued with adequate doses of the drug

Digitalis vomiting does not depend solely on the dosage It occurs in some patients even after small amounts of digitalis while in others relatively large amounts fail to induce it Therefore one is not permitted to consider the appearance of vomiting as a sign that the patient is fully digitalized

Anorexia nausea and diarrhea may also occur

Salivation Fatigue and Other Signs Neuralgic symptoms with shooting pains tingling of the fingers and generalized muscular pains have been described (Batterman and Gutner) Delirium may appear (Duroziez King) caused by injury to nerve cells Gynecomastia is found because of the action of the aglucones (LeWinn)

Other untoward effects described by Withering are increased salivation and great lassitude The latter appears particularly in elderly patients who also suffer occasionally from headaches delirium hallucinations and convulsions

Visual Disturbances Green and yellow vision is common blue and red vision is rare Dimness of vision inability to focus scotomata and even temporary blindness are occasionally observed

Eosinophilia A marked eosinophilia appears in the blood in some patients allegedly through an increase of vagal tonus (Pecht Romano and Geiger) Up to 30 per cent eosinophiles have been observed during digitalization

Anuria Anuria due to digitalis is rare but undoubtedly occurs In one of our patients with lead poisoning hypertension and nephrosclerosis the administration of four tablets of 0 1 Gm digitalis daily led to oliguria and water retention After the drug was discontinued for 2 or 3 days there was a profuse diuresis and a weight loss amounting to 5 Kg The experiment was repeated a few times with the same result Intravenous injection of ¼ mg of strophanthin daily had the same effect (Hauser and Scherf)

Coagulation of Blood In therapeutic doses digitalis was said to alter the coagulability of the blood With no change in the prothrombin time coagulation time was shortened (Massie et al) The frequent occurrence of venous thrombosis in cardiac cases has been ascribed to this effect of digitalis This effect of digitalis on the coagulation time has been denied recently (Sokoloff and Ferrer) but fast energetic digitalization is still said to increase the incidence of thromboembolism (Cormsen)

Extrasystoles Experimentally cardiac irregularities appear in cats after 75 per cent of the fatal dose of digitoxin and 60 per cent of the fatal dose of oubaine are given This includes conduction disturbances (Krueger and Unna)

A very important sign of so called digitalis intoxication is the appearance of extrasystoles They are usually found as bigeminy that is every normal beat is followed by an extrasystole We put intoxication in quotation marks because healthy mammalian hearts do not develop the regular digitalis bigeminy even when treated with toxic doses It was not possible to observe this disturbance

of rhythm in man following the administration of toxic doses (suicides) or in animal experiments as long as the heart was in good condition Only the dying heart may show bigeminal groups in the very last minutes before standstill Extrasystoles like those observed in the cardiac patient which may persist for weeks are obtained experimentally however if the myocardium is chemically or mechanically damaged (Kobacker and Scherf) In a similar way digitalis causes extrasystoles in patients only if myocardial damage coexists The nature of this myocardial damage the necessary prerequisite was unknown until recently If extrasystoles develop during digitalis therapy in a cardiac patient it indicates that the heart muscle is abnormal Accordingly the prognosis is always dubious

Recent investigations show that a diminished amount of potassium in the heart muscle cells is responsible Skeletal and heart muscle lose some potassium when fatigued Toxic doses of digitalis have the same effect whether the therapeutic doses do so is not certain but possible The potassium content of the heart muscle was found diminished particularly in mitral lesions with chronic heart failure (Calhoun et al) it is usually in these hearts that digitalis bigeminy appears Lown could elicit digitalis extrasystoles when potassium was removed from the serum by hemodialysis and Page could precipitate ventricular arrhythmias in 7 of 37 digitalized patients by reducing the potassium level in the serum through the administration of carbohydrates Anoxia acidosis adrenalin insulin and glucose injections increase the potassium deficit in the heart Since it is not only the amount of digitalis but also the state of the heart muscle that is important for the development of these extrasystoles the term sign of intoxication in the usual sense is not entirely justified Some patients do not develop digitalis extrasystoles even if they take 0 2 Gm of standardized leaf daily for years while others develop them regularly after the third *tablet* of 0 1 Gm digitalis (personal observations) Five to seven grams of potassium chloride daily in fruit juice abolish these extrasystoles

Extrasystoles and bigeminal rhythm may occur in cardiac patients independent of digitalis treatment In these cases digitalis therapy — if indicated — is permissible and one will usually find that the extrasystoles disappear during the treatment In patients who show extrasystoles in the course of digitalis therapy however great caution should be observed before further doses of the remedy are administered If the treatment is continued in the presence of extrasystoles caused by digitalis the number of extrasystoles often increases resulting in the development of threatening tachycardias and even ventricular fibrillation If digitalis treatment seems necessary one may continue the treatment with small doses i e not more than 0 15 Gm daily The patient must be examined at least twice daily and the treatment must be discontinued if the number of extrasystoles increases Most — if not all — deaths due to the administration of digitalis are caused by the neglect of this rule In an advanced stage digitalis extrasystoles occur so irregularly and so rapidly that an anarchie ventriculaire appears (Mahaim) the examining physician is convinced that

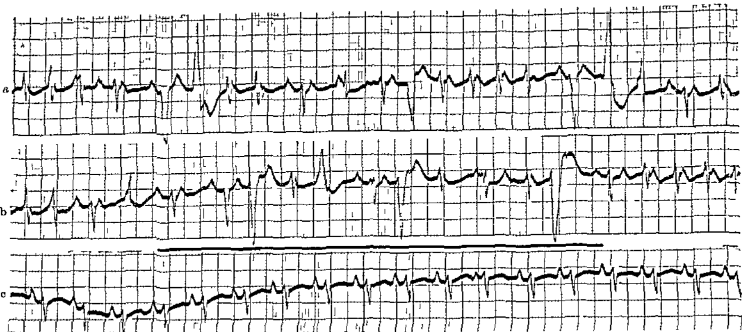

FIG 116 The top tracing (lead II) shows an atrial ectopic tachycardia and partial A V block in a 70 year old woman who had received 1 mg of digitoxin as a single dose Ventricular extrasystoles are also present In (b) the tachycardia remains during carotid pressure (the horizontal black line indicates the duration of pressure) it persists when pressure is discontinued Figure 116c shows a regular sinus rhythm interrupted by a single atrial extrasystole 11 days *after the digitalis* had been stopped and after the administration of potassium

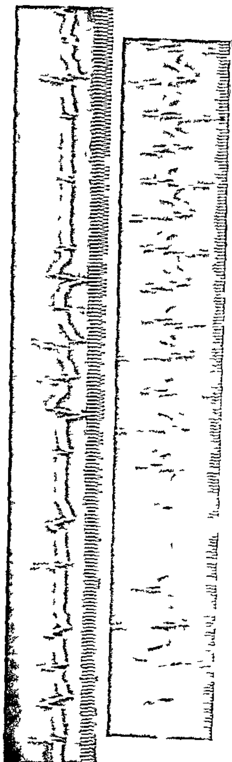

Fig 117 Fig 118

Fig 117 Atrial fibrillation and multiform ventricular extrasystoles with abnormal idioventricular ectopic beats caused by digitalis

Fig 118 Ventricular tachycardia with alternating form of ventricular complexes caused by digitalis There is also atrial fibrillation

he is dealing with atrial fibrillation and rapid ventricular action he increases the dose of digitalis and ventricular fibrillation is induced The principal reason that *the treatment with full therapeutic doses* — the administration of large amounts of digitalis in one or two doses — should be completely abandoned is that one can never predict after what dose of digitalis extrasystoles will appear Since they may develop even after a few *tablets* the administration of large initial doses may lead to dangerous and even lethal arrhythmias It is therefore understandable that most publications dealing with dangerous digitalis arrhythmias appeared when treatment with full doses was in vogue about forty years ago and again in recent years

Digitalis extrasystoles usually originate in the ventricles Reports of atrial extrasystoles caused by digitalis are scarce We have rarely seen them In all probability the reason for this rarity lies in the fact that the atria are under the influence of the increased inhibitory vagal tonus during digitalis therapy and this influence is lacking in the ventricles Experimentally the direct application of digitalis (or strophanthin) to the myocardium leads to atrial as well as to ventricular extrasystoles

Paroxysmal atrial tachycardias with partial A V block appear during the administration of

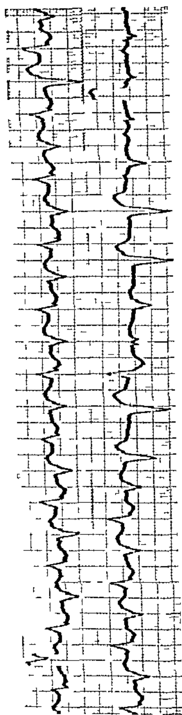

Fig 119 Ventricular tachycardia with alternating forms of the ventricular complexes in a patient with sinus rhythm The patient died suddenly presumably from ventricular fibrillation a few hours after the record had been registered

digitalis and disappear promptly after the exhibition of potassium chloride or acetate (figure 116)

The electrocardiogram usually permits the differentiation between digitalis extra systoles and the harmless ventricular extrasystoles that occur in the healthy The extrasystoles found so often in the healthy always originate in the same focus and show the same ventricular elec trocardiographic complex even if they persist for years Extrasystoles due to digitalis show a continuous variation of form since they originate in different foci and are due to an abnormal intraventric ular conduction (Scherf 1927) Extra systoles caused by organic heart disease (coronary sclerosis diphtheria) may also show varying forms of the ventricular complexes

This initiation of ectopic impulses by digitalis is a specific quality of the drug and is not caused by increased excitabil ity the latter is actually diminished

Figure 117 shows the electrocardio gram in the third lead of a patient with a rheumatic mitral lesion and extra systoles due to digitalis There is atrial fibrillation The first ventricular com plex conducted from the atrium in the tracing is followed by three multiform ventricular extrasystoles the second by one The third conducted complex is fol lowed by six extrasystoles and then by an abnormal automatic beat which is a characteristic digitalis effect

In figure 118 obtained from an other patient atrial fibrillation is also present (lead II) The first beat is fol lowed by three ventricular extrasystoles of different form The next beat after a pause is followed by a paroxysmal ventricular tachycardia with alternating form of the ventricular beats These

tachycardias precede the stage of ventricular fibrillation They are rarely seen except when digitalis is used in advanced myocardial damage They appear typically however if digitalis therapy is continued in cases of digitalis bigeminy

The important phenomenon of redigitalization is discussed in the next section

Elderly patients tend to show untoward effects after administration of moderate doses more often than younger individuals (fig 119)

Dosage

It is not advisable to follow a fixed scheme of treatment The digitalization of every new patient represents an experiment with an unknown outcome One can never know in advance how much digitalis a patient will need Only after it is determined how the patient responds to treatment how much digitalis is needed to obtain a desired effect and how long it takes until compensation is restored should an opinion about the prognosis of a decompensated case be offered

Full Dose Treatment As was previously mentioned and for the reason just cited the practice formerly in vogue and recently reintroduced of treating every decompensated cardiac patient for a certain number of days always with the same amount of digitalis is not correct It is just as improper to give schematically an amount of digitalis calculated according to body weight This is done by pharmacologists in animal experiments but is not permissible in the sick patient whose reaction to digitalis treatment is unpredictable

In recent years a similar method the full dose therapy was recommended Without regard to weight age or degree of failure the dose of 1 2 mg of digitoxin is given at one time Others recommended 1 7 or even 2 2 mg is the full dose The statement that 1 2 mg of digitoxin may be given at one time with complete safety (Gold et al) is certainly wrong as many publications show On the other hand Evans et al give 2 mg of digitoxin to one patient without even obtaining a slowing of the rate

Four facts speak against this procedure In the first place patients with the same type of heart lesion of the same age and the same body weight and even the same degree of decompensation may require entirely different amounts of digitalis Furthermore the wisdom of administering large doses to restore compensation as quickly as possible may be doubted Naturally one wishes to help as soon as possible and to improve the cardiac condition in an emergency Nevertheless the average cardiac patient who requires digitalis for rapid ventricular action caused by atrial fibrillation or for decompensation does not have to be digitalized within 24 hours The old mechanical conception of decompensation no longer suffices We have learned that most tissues and cells of the body live under abnormal conditions in a patient with congestive heart failure the advantage of changing the situation quickly is questionable Nothing is gained by restoring the circulation in these patients within a few hours instead of a few days indeed the disadvantages are great The third and most important reason for

not utilizing the "full dose" treatment was mentioned in the preceding pages when it was pointed out that the appearance of dangerous extrasystolic arrhythmias even after small doses of digitalis can never be foreseen. Finally, caution against the employment of large doses is required because focal necrosis appears in the myocardium in the experimental animal after the administration of sublethal doses of digitalis. While similar changes have not been observed in man even after the use of large therapeutic doses, one should not forget that injury to the tissue cells may occur despite the fact that such injury may not be demonstrable by our rather crude histologic methods.

Actually severe signs of intoxication have been seen, particularly in elderly patients, even after the administration of 0.6 mg. of digitoxin (Fremont and King). We have seen toxic prefibrillatory arrhythmias and atrial tachycardias after 0.3 mg. of digitoxin daily, and the lassitude and nausea may persist for weeks.

Not only does every species of animals have a different sensitivity to digitalis, but the sensitivity of different members of the same species of healthy laboratory animals varies. This is true much more for sick human beings who at different times need different doses.

Furthermore, a "half dose" in a patient with atrial fibrillation brings the rate down from 160 to 85, while the "full dose" brings the rate down from 160 to 75 in the same patient (Kay). The dangers of larger doses are infinitely greater. The benefit is small.

There is no "average" initial or maintenance dose except that which is calculated on paper. Therapy is highly individual. Therefore, the recent revival of the "full digitalizing dose," assuming that the amount needed by every individual is the same independent of weight, age, etc., cannot be accepted.

Initial Dosage. While treatment with excessively large doses of digitalis given within a short time should be avoided, the administration of moderate doses proportionate to the severity of the decompensation is proper.

One tenth of 1 Gm. of the standardized (assayed) powdered leaves in the form of tablets will be considered as a standard unit. Even here the strength may change. Thus, the assayed digitalis of USP XI was much stronger than that of USP X, while the digitalis of USP XII was again slightly weaker.

The dose given to a patient with mild decompensation who does not present severe manifestations of congestion may amount to 0.15—0.2 Gm. a day of assayed digitalis in the form of powdered leaves or tablets. In more severe cases of decompensation the daily dose is increased to 0.1 Gm. three or four times daily.

Only those subjects who are known to require much larger doses of digitalis than the average patient should receive about 0.6 Gm. of digitalis daily. This group comprises patients with hyperthyroidism, fever, or pulmonary embolism. The literature on the question of the greater resistance to digitalis of patients belonging to one of these groups is large and somewhat contradictory. It seems established, however, that slowing the heart in patients with hyperthyroidism combined with atrial fibrillation is difficult. Why a larger amount of digita needed by virtue of the presence of fever is not yet decided. Another une

difficulty in obtaining the desired slowing of the heart in atrial fibrillation is encountered in patients with pulmonaray embolism This complication should always be suspected if — in the absence of fever or hyperthyroidism — the expected effect of digitalis is not obtained

Large doses of digitalis are given only as long as evidence of severe decompensation persists As soon as improvement appears treatment is continued with smaller doses

One can never predict the duration of digitalis therapy Many days or even weeks may elapse before it appears that the best possible result has been obtained or until digitalis vomiting or bigeminy prevents further administration of the drug Long duration of the period of digitalis medication in itself is no contraindication for continuation of the treatment

Maintenance Treatment If digitalis therapy in a decompensated lesion or myocardial disease is carried to the point where the patient seems fully compensated and all signs of congestion have disappeared or when this result is impossible if the optimal state seems to exist the administration of digitalis should not be discontinued to be resumed only when the manifestations of decompensation reappear It is also improper to recommend a certain amount of digitalis purely schematically for a number of days each month for all patients It is better practice with most patients not to pause entirely in the administration of the drug an adequate amount should be given to maintain the patient in the best condition attainable by treatment

In cases of atrial fibrillation in which digitalis is given only to keep the ventricular rate low the rate itself is the best guide for the dosage These cases in particular require maintenance treatment Patients who develop decompensation following an acute infection or excessive physical effort may not require maintenance treatment Full compensation may be preserved if the cause for the decompensation has vanished

The dose for maintenance treatment should also vary according to the needs of the patient If compensation was readily restored and if this was achieved with relatively small doses of digitalis 0 1 Gm digitalis given once on every day or on every second day may suffice If larger doses were originally required for a long period the maintenance doses also will usually be larger One will find that some patients may need 0 2 or even 0 3 Gm of digitalis every day because even a temporary and slight reduction of the dose causes the reappearance of signs of decompensation Naturally the amount of digitalis required by the individual patient will not always be found instantly after some observation the doses may have to be increased or decreased Likewise the unavoidable alteration of the sensitivity of the patient changes of the heart and also changes of the strength of the drug may force a change of dosage Digitalis made by different manufacturers which were assayed cause quite different responses in man at different times and in addition the absorption and stability of different preparations varies

For these reasons patients who require maintenance treatment with digitalis need periodic re examination by their physicians By the continuous adminis

tration of digitalis patients avoid the frequent change from compensation to decompensation and within certain limits they may be kept active for years There is no danger of acquiring tolerance for digitalis from prolonged administration the drug always remains effective

If some untoward sign mentioned in a previous chapter including digitalis extrasystoles appears and one finds that continued treatment is necessary merely diminishing the dose often will suffice If the patient does not tolerate even the smallest doses without exhibiting side effects one may be compelled to stop the drug completely and try again after a short period during which other cardiac stimulants such as caffeine or theophylline are given

Different Preparations of Digitalis

In selecting a preparation it should be remembered that the galenic forms of digitalis are still among the most reliable provided the assayed drug is employed

The powdered leaf or the tablet made from powdered leaves are most commonly used Formerly digitalis tincture was used widely if fresh it is very satisfactory It is rarely prescribed at present and perhaps should be avoided because it must be fresh and reliable in order to give good results The deterioration of tablets or powdered leaves by storage is negligible

The number of special digitalis preparations on the market is legion and new ones constantly appear Most of these preparations are satisfactory Few have any advantage in comparison to assayed digitalis tablets If a new preparation is tried the physician should familiarize himself with the correct dosage which is frequently at variance with the manufacturer s recommendation Only experience gained by the use of the preparation in many patients will show its value It is unwise for the physician to change continually to new and different preparations and to adopt at once those which are highly eulogized Certain advantages are claimed for every new preparation of digitalis Many of these attributes to be sure are based on experimental investigations on the frog or cat heart and have little value at the bedside If it is asserted that a preparation is nontoxic does not cumulate and does not produce vomiting it should not be employed it is inert A good preparation of digitalis is toxic does cumulate at least to a slight degree and must cause vomiting when it is administered in sufficiently large doses

Preparations of digitalis made from the whole drug (Digifortis Digalen Digilanid Digifolin and many others) contain a mixture of glycosides and possess no advantage over the standardized preparations they are rarely used in the United States today They may be used where the standardized powder or tablets are unobtainable The physician is advised to employ only one or two of these preparations in order to obtain some experience Even the strength of these special preparations may change for various reasons and a physician who does not thoroughly know the digitalis employed may become aware of this change too late It is a great handicap to work with two unknowns the preparation of digitalis *and* the patient

Most good commercial preparations are assayed One should not rely however too strongly upon the statement of the manufacturer for dosage The amount should be determined on the basis of personal experience If the directions printed on packages are followed the dose prescribed frequently is too small

Every physician should be acquainted with the action of a few special preparations of digitalis Some are very powerful Since some are obtainable in the purified crystalline state the dosage is exact and the biologic assay with all its difficulties is unnecessary

The oldest pure crystalline digitalis glycoside is digitoxin (digitaline Nativelle) It is quantitatively absorbed when given orally The different preparations of digitoxin are not of equal purity and not of equal strength A dose of 0 1 mg given three times daily is as active as three tablets of 0 1 Gm powdered leaves given daily Only for special purposes e g to transform atrial flutter into fibrillation should larger doses be given and then only under close supervision Nausea and vomiting soon appear with large doses Digitoxin is fixed to the albumin fraction in the blood and disappears completely from the blood only after 24 hours It is therefore not one of the rapidly acting glycosides Only 7 per cent of the glycoside is dissipated daily in the heart muscle Therefore digitoxin is a glycoside with a great tendency to cumulate For the restoration of compensation in patients with coronary sclerosis or following a myocardial infarction preparations of digitoxin are very useful In many patients the prolonged administration of 0 2 mg daily is necessary to preserve compensation In others particularly in elderly people this dose is too large and causes toxic phenomena to appear Some patients need 0 1 mg every other day or even smaller amounts

A very satisfactory glycoside isolated from digitalis lanata is the crystallized digoxin (Smith) It can be given by mouth or by injection Following an intravenous injection ventricular slowing begins in five to ten minutes and the maximum effect is attained within an hour After oral administration improvement begins within an hour and may be pronounced within six to seven hours Tablets contain 0 25 mg of digoxin and the material for injection contains 0 5 mg per ml

The third crystalline glycoside also isolated from digitalis lanata is Cedilanid (lanatosid C) The components originally isolated (digilanides) were found to cumulate less than digitoxin Ampules and tablets are available One ml of the liquid contains 0 2 mg of Cedilanid The first dose is usually 2—4 ml It may be repeated on the next day according to the condition of the patient

Lanatosid C is bound but little to blood proteins and acts quickly almost like strophanthin It is rapidly eliminated

Acetyl digitoxin is also derived from the digitalis lanata It is obtained from lanatosid A fraction by enzymatic cleavage of 1 molecule of glucose It is absorbed rapidly Therefore it is recommended particularly for paroxysmal tachycardias and fibrillation (Loeffler et al)

Citalin a mixture of amorphous digitalis glycosides that has been employed on the European continent for many years recently has been reintroduced (Batter

man) We employed it for many years as Verodigen and found it reliable However the claim that gitalin (amorphous) helps when other glycosides fail is unjustified

Method of Administration

In the majority of cases digitalis is given by mouth in the form of the assayed powder tablets drops or pills of one of the reliable commercial preparations In exceptional cases in which more rapid effects seem necessary digitalis is given intravenously using a crystallized pure glycoside (digitoxin digoxin cedilanid)

The rectal suppository represents another method of administration but it is rarely used in this country By rectal administration of purified digitalis gastric irritation due to ballast substances and saponins is avoided Furthermore the drug is absorbed by the mucosa and conducted by the hemorrhoidal veins into the inferior vena cava without retention in the liver The rectal administration of digitalis has the same effect as a slow intravenous infusion The amount of digitalis which should be given by rectum is the same as that which would be given by mouth

It is easy to administer the whole dose of digitalis for the day in the form of two suppositories in this way one obtains better absorption without gastric irritation Particularly in those patients who present evidence of marked hepatic congestion or who for some reason are unable to receive injections of a crystalline digitalis glycoside or strophanthin suppositories are useful

One of the best is the digilanid suppository If a dose or a preparation different than that obtainable from the manufacturer is desired the suppositories can be prepared by any pharmacist by mixing the corresponding amount of a purified digitalis preparation (digitaline digalen digilanid) with cacao butter Usually it is possible to mix about 15 drops of an appropriate digitalis solution in the amount of cacao butter required for one suppository

Another advantage of a suppository is the possibility of admixing other substances which must be administered by rectum Thus patients with Cheyne Stokes breathing may need aminophylline in addition and if necessary an hypnotic may be added For example

Digalen	0 5 ml
Aminophylline (Theophylline ethylendiamine)	0 5 Gm
Ol Cacao q s f suppos	

One suppository may be given in the morning and sodium phenobarbital may be added to another which may be administered in the evening

It is not advisable to administer digitalis intramuscularly since local pain invariably follows and the temperature rises indicating muscular necrosis

Preparations with Digitalis Like Action

There is a large number of so called digitalis preparations of the second order they are powerful and active drugs Most of these preparations have effects similar to those of digitalis but rarely do they accomplish more than digitalis In the rare case of idiosyncrasy to digitalis such agents may be em

ployed we find them useful on patients who are under the impression that the administration of digitalis means the beginning of the end

Squill is perhaps the best known representative of this group It is at the same time one of the oldest known drugs being mentioned in the Ebers papyrus From the drug a pure crystallized glycoside, Scillaren A has been isolated (Stoll) and its activity can be compared with good preparations of digitalis The single dose of Scillaren by mouth is 0 8 mg the suppositories contain 1 mg of the glycoside The side effects if these drugs are employed are the same as those of digitalis including ventricular extrasystoles

Among the other drugs of this group (Adonis vernalis Nerium Antiaris Convallaria majalis) only Helleborus deserves mention Its purified extracts proved very active in its pharmacologic characteristics it stands midway between digitalis and strophanthin (Scherf)

STROPHANTHIN

Closely allied to the digitalis glycosides although different in many respects are the glycosides of strophanthus Of the many compounds in this group only three are used clinically

Preparations

K Strophanthin Strophanthin kombè or k strophanthin is an amorphous powder In recent years it has been possible to isolate a crystalline glycoside from k strophanthin which represents about three quarters of the amorphous glycoside It is called strophoside K strophanthin is mentioned in the United States and in the British Pharmacopoiea and it was widely used in Germany under the leadership of Fraenkel

G Strophanthin Strophanthin gratus or g strophanthin was isolated as a more stable crystalline product by Arnaud (1888) and is called by its African name ouabain This preparation is widely used in French medicine

Acetyl strophantidine an aglucone is a synthetic preparation prepared from the seeds of strophanthus kombe It works more rapidly than any other preparation and therein lies its danger Toxic rhythms are common and in our opinion there is no place for the use of this compound in clinical medicine

Pharmacologic Effects

The action and side effects of strophanthins on the heart muscle particularly on systole and on the blood vessels are identical to those of digitalis Some of the differences are their great solubility in water the small amount of fixation of strophanthin in the heart and — in connection with this — the slight cumulation If a dose of digitoxin is given 93 per cent of the drug is still present in the heart after 24 hours and 50 per cent after 9 days Of a dose of lanatoside C after 24 hours only 80 per cent is present and only 64 per cent after 48 hours Of strophanthin only 50 per cent of its action is present after one day and only

one eighth after three days (Rothlin and Bircher) The most important difference from a clinical standpoint has been the almost immediate action of strophanthin This is advantageous when it is necessary to improve a severe decompensation rapidly With the pure crystalline glycosides of digitalis purpurea (digitoxin) and digitalis lanata (digoxin cedilanid) which may be given intravenously only slightly less rapid action (30—60 minutes) is obtainable

There are few potent drugs about which opinions are as divided as strophanthin (Kisch) While in some countries particularly on the European continent strophanthin is employed in practically all types of decompensation much more often than digitalis and in many large institutions seems to be the drug of choice in other countries strophanthin is scarcely known

Several facts account for this difference of opinion First overenthusiastic physicians stressed the digitalis like effect of strophanthin and went so far as to use it as a synonym for digitalis neglecting however to stress the important and essential differences between the two Second the doses recommended (even in recent times) were much too large led to untoward effects and discouraged the physician from further use Third most preparations of strophanthin are quickly destroyed particularly by the alkaline glass of the ampules and lose their potency within a short time Therefore many preparations now dispensed are disappointingly weak unless certain types of glass are used for the containers If injection of the inactive contents of these ampules a few times in emergencies elicits no effect the disappointed physician doubts the reports of other observers and decides to use only digitalis in the future

The ampules of ouabain at present are the best preparation of strophanthin obtainable in this country

Indications

In general strophanthin is indicated in the same conditions as digitalis Since these preparations are active only if given by injection there is the disadvantage of greater expense to the patient for he is forced to have an injection daily or almost daily for some time accordingly we feel that for routine treatment digitalis is by far preferable and that strophanthin should be given only on definite indications

Formerly the fact that its exact dosage could be prescribed without the necessity of bioassay was of great advantage but such procedure is also possible now with the crystalline preparations of digitalis

Strophanthin is indicated in an acute emergency If for example in an untreated or inadequately treated pregnant woman with mitral stenosis acute heart failure appears during childbirth or if a protracted and severe pulmonary edema appears in a patient with hypertension and does not react well to symptomatic therapy or if a patient is admitted to the hospital with a surgical emergency requiring immediate operation and atrial fibrillation with a very rapid ventricular rate is found the administration of strophanthin will usually bring noticeable improvement within a few minutes However it must be stressed

is present due to pulmonary congestion In these cases rapid dehydration may furnish quick relief In the majority of cases however treatment with diuretics is initiated only after the circulation has been improved somewhat by digitalis Often even the strongest diuretics evoke only a slight response when given to congested and decompensated patients If diuretic treatment is delayed a few days until the circulation is improved somewhat by digitalis striking effects may be obtained with much smaller amounts of diuretics Often the diuretics even become superfluous because rest in bed diet and digitalis alone cause a profuse diuresis

The diuretics *which are the most effective and if properly employed* distress the patient least by unpleasant untoward actions particularly on the gastrointestinal tract are certain organic preparations of mercury Since their use is not permissible in some cases every physician should be acquainted with the xanthine derivatives and other diuretics as well The action and the method of administration of the latter preparations will be considered first

Xanthine Derivatives

Xanthine preparations (purine bodies) have caffeine theobromine and theophylline as chief representatives While caffeine exerts its strongest effect as a stimulant of the central nervous system theobromine and theophylline are pronounced diuretic agents They also dilate the coronary arteries

All these preparations increase water and sodium chloride diuresis This effect seems to be accomplished by a direct action on the kidney Diminished tubular absorption has been assumed partly it is due to improved contractility of the heart and to mobilization of water and salt in the tissues Vasodilatation and better perfusion of the kidney originally held responsible seem to play a minor role All these drugs also stimulate the heart Thus theophylline increases the output of the damaged heart of the dog in the Starling preparation This effect is independent of changes of the coronary blood flow

Caffeine is rarely used as a diuretic since its stimulating action on the central nervous system is so pronounced that it leads to unpleasant sensations

The xanthine preparations most commonly used as diuretics are theobromine and its salts or *theophylline with various combinations*

The customary method of administering moderate doses of xanthine bodies distributed throughout the day often produced little diuretic action It is better not to scatter the doses rather large amounts should be used at short intervals and only for a short time

If the diuretic effect of one of these drugs ceases there is no justification for continuing the remedy with larger doses It is better to prescribe another preparation which may act excellently although it may be closely related to that which was originally given

Pure Theobromine In using pure theobromine we observed the best effect when it was given in [illegible] after lunch and if the same dose was repeated

two and four hours later thus a total of 3 Gm are given in divided doses in the afternoon If patients become too stimulated by the drug and sleep is disturbed theobromine may be administered after breakfast and two as well as four hours later

Theobromine Calcium Salicylate This drug known under the name Theocalcin is said to cause less gastrointestinal disturbance but we found no difference in comparison to some of the other purine bodies The dose is 3 Gm daily

Theophylline The strongest diuretic effect is obtained with pure theophylline It is best to administer it in enteric coated tablets similar tablets are also available for some of the other xanthine preparations The diuretic effect of theophyllinum purum is much stronger than that of theophylline with ethylendiamine (aminophyllin euphylline) or theophylline with sodium acetate The rule of giving large doses within a relatively short time is particularly applicable with this preparation The best diuretic effect is obtained if 0 3 Gm is given after meals three times a day but only on every fourth day Such jolts of theophylline are greatly superior to small doses daily The 24 hour diuresis may amount to 5 liters Sometimes pure theophylline given in this way may be effective when mercurial diuretics fail (Faltitschek and Scherf)

If the preparation is used in the same dosage daily its diuretic effect often ceases completely within a few days If administered only on every fourth day as is the case with the mercurial diuretics it remains active for an indefinite period

Vogl recommends 0 5 Gm of aminophyllin injected intravenously twice daily very slowly for the purpose of diuresis

Untoward Effects Whenever xanthine preparations are administered it is well to inform the patient that untoward effects may occur In the event that such phenomena appear the patient is not taken by surprise and is not alarmed Moreover he is informed in advance that discontinuance of the remedy will afford rapid relief If the patient is unacquainted with the possibility of unpleasant untoward reactions the appearance of nausea vomiting severe headache and restlessness with increased excitability may be alarming All these phenomena are more common with theophylline than with other xanthines To counteract the central stimulating effect the administration of phenobarbital (0 03—0 05 Gm) with each dose of theophylline is recommended

A rare but nevertheless important contraindication to theophylline is epilepsy The preparation stimulates the cerebral cortex and may lead to attacks in epileptic individuals This effect as well as headache and hyperirritability are also prevented or diminished by the addition of phenobarbital to each dose of theophylline

Antidiuretic Action of Sedatives Analgesics and Hypnotics

Phenobarbital in the doses mentioned does not depress the diuretic action of theophylline Larger doses however as well as moderate doses of morphine or aminopyrine may not only abolish the effect of diuretics but may also inhibit normal diuresis to a high degree

is present due to pulmonary congestion In these cases rapid dehydration may furnish quick relief In the majority of cases however treatment with diuretics is initiated only after the circulation has been improved somewhat by digitalis Often even the strongest diuretics evoke only a slight response when given to congested and decompensated patients If diuretic treatment is delayed a few days until the circulation is improved somewhat by digitalis striking effects may be obtained with much smaller amounts of diuretics Often the diuretics even become superfluous because rest in bed diet and digitalis alone cause a profuse diuresis

The diuretics which are the most effective and if properly employed distress the patient least by unpleasant untoward actions particularly on the gastrointestinal tract are certain organic preparations of mercury Since their use is not permissible in some cases every physician should be acquainted with the xanthine derivatives and other diuretics as well The action and the method of administration of the latter preparations will be considered first

The xanthine preparations most commonly used as diuretics are theobromine and its salts or theophylline with various combinations

The customary method of administering moderate doses of xanthine bodies distributed throughout the day often produced little diuretic action It is better not to scatter the doses rather large amounts should be used at short intervals and only for a short time

If the diuretic effect of one of these drugs ceases there is no justification for continuing the remedy with larger doses It is better to prescribe another preparation which may act excellently although it may be closely related to that which was originally given

Pure Theobromine In using pure theobromine we observed the best effect when it was given in doses of 1 Gm after lunch and if the same dose was repeated

The administration of potassium salts as diuretics has been revived in recent years Potassium chloride or acetate are recommended Doses of about 5 Gm daily seem to be optimal Potassium chloride is obtainable in enteric coated tablets Occasionally nausea occurs during the administration of the drug and methemoglobinemia has followed the use of potassium nitrate If large doses are used or if kidney function is impaired the level of blood potassium increases The acid base balance is changed in some patients toward the acid side

Mercurial Diuretics

Type of Preparations Some inorganic mercurial preparations e g calomel have been used for many years as diuretics The action of calomel however was unreliable and intoxications were frequent The discovery of the diuretic action of organic soluble salts of mercury in 1920 was one of the greatest advances in the treatment of cardiac patients in recent years The duration of life in many patients is prolonged for years and countless others are enabled to lead an active life with the employment of these drugs The discovery was quite accidental Novasurol (Merbaphen) was used for about three years in the treatment of syphilis until its diuretic action was observed in a case of syphilitic aortitis (Saxl and Heilig Vogl) Later Salygran (mersalyl) and novurit (Mercupurine Mercurin) were introduced as well as neptal esidrone Mercuhydrin Thiomerin and others It is often claimed that the first preparation Novasurol (Merbaphen) was more toxic than the others but it seems that as experience increased the preparations were used more cautiously and therefore toxic manifestations became rare These diuretics contain about 40 mg of mercury per ml

Since the introduction of Mercupurine (novurit) which contains a very small amount of theophylline it has been claimed that this addition considerably enhances the diuretic effect of the mercurial salts Therefore theophylline was also added to most of the other preparations It is claimed that the addition of theophylline makes the mercurial diuretic less toxic and that they are less irritating locally when injected intramuscularly At bedside in appropriate cases by alternating the use of mercurial diuretics with and without theophylline we were unable to discover an appreciable difference

Fundamentally the diuretic action of all above named mercurial preparations is equal It has been claimed however that some such as neptal and esidrone are slightly more toxic than the others Mercupurine seems to act a little sooner and diuresis follows the injection more rapidly But the end result is the same as with the other diuretics The remarks which follow are equally applicable for all preparations including Mercuhydrin and Thiomerin which is a mercaptan compound and which can be given subcutaneously

Pharmacology The preparations lead to a marked water diuresis and to a relative and absolute increase of the sodium chloride diuresis More than 40 Gm of sodium chloride may be excreted in 24 hours In a boy of 15 years 1 ml of neptal caused a diuresis of 14 430 ml of urine in 24 hours 570 ml of urine were

in the urine of patients with congestive heart failure is increased The presence of a concentrated dark urine (after exposure to air for a few hours) due to urobilin shows that it is safe to use mercurial diuretics

The presence of colitis in any form constitutes another contraindication to mercurials Colitis is one of the most dangerous manifestations of mercury intoxication and therefore the administration of these compounds should be avoided when colitis is already present It is also unwise to give purgatives which irritate the large intestine on the days of the injection of mercurial diuretics Decayed neglected teeth and the presence of a profound anemia or cachexia are further contraindications since mercurial diuretics have a relatively high content of mercury and therefore act as cell poisons

Untoward Effects Mercurial diuretics may cause untoward effects by different mechanisms those of mercury intoxication those due to hypersensitivity or those caused by a too marked loss of water and electrolytes

MERCURIALISM The earliest indications of mercury intoxication are metallic taste salivation gingivitis stomatitis and colitis The latter is often hemorrhagic in character The patient may collapse so suddenly that no melena occurs All these manifestations of mercurial intoxication were rare since the preparations were used with proper caution and in appropriate cases Unfortunately it has been recommended recently that mercurial diuretics be given in intervals that prove to be too short with the result that evidence of intoxication is observed more often Agranulocytosis may occur

To counteract the effect of mercury BAL (5 mg per Kg) is given intravenously every 4 hours

HYPERSENSITIVITY Hypersensitivity to the mercury ion may exist but more often it is connected with the specific organic compound used Therefore change of the preparations often helps to avoid further abnormal reactions Dizziness fall of blood pressure drowsiness and headaches urticaria and erythematous dermatitis may appear fever collapse and cyanosis with death in a few minutes have been observed Dyspnea and attacks of asthma have followed even the first injection There is experimental and clinical evidence that ventricular extrasystoles paroxysmal tachycardias and ventricular fibrillation may appear owing to the direct effect of the mercury ion on the heart muscle These effects particularly the cardiac arrhythmias appear for the most part after intravenous injections

CONSEQUENCES OF DIURESIS The loss of water sodium and chloride causes somnolence cramps in the calf muscles and sometimes delirium or mental confusion Profound weakness may appear due to loss of potassium Therefore fruit juices should be ordered These complaints were known to follow a profuse diuresis long before the mercurial diuretics were introduced Since the excretion of sodium and chlorides need not parallel the water diuresis occasionally one observes these phenomena after moderate diuresis but may miss them after an unusually profuse one

The loss of calcium ions may lead to tetany Acute gout has appeared in a series of patients who had had previous attacks of gout A disturbance of electrolyte balance may be responsible

It has been claimed that the influx of fluid from the tissues increases the coagulability of the blood and therefore increases the danger of thrombosis and embolism

Fever and cutaneous manifestations (rash) may develop after an injection The fever may reach 39 C but rarely lasts longer than 24 hours the simultaneous use of calcium gluconate may help avoid these complications

However the intravenous injection of calcium preparations is dangerous especially in digitalized patients In one personally observed case it was followed by ventricular fibrillation in another patient who had not received digitalis before a long and dangerous ventricular standstill instantaneously followed the injection Intramuscular injections of calcium salts are free from these dangers

The appearance of abnormal reactions cannot be predicted They have been observed in patients who responded normally to preceding injections If however an abnormal reaction occurs once it is unwise to employ the intravenous route Sudden lethal accidents are not observed after intramuscular injections of mercury

While collapse or even sudden death immediately following an injection due to allergy undoubtedly occurs such catastrophes are rare and should not militate against use of these excellent agents Several series of more than 8000 injections have been reported without the occurrence of any untoward effect

The profuse diuresis may lead to an acute urinary retention in elderly patients with prostatic hypertrophy

Two other side effects of therapy with mercurial diuretics merit attention

(1) THE LOW SALT SYNDROME This develops in patients who receive mercurial diuretics too often while on a salt free diet or when losing much salt from the kidney The diuresis in these patients stops and they gain in weight they have low plasma levels of sodium (from 140 to 120 mEq per liter or less) and chlorides (from 100 to 86 mEq per liter or less) drowsiness and weakness may appear simultaneously Nausea and vomiting may occur and abdominal cramps are common There is a low carbon dioxide combining power and the urea as well as the NPN are increased often to values over 100 This acidosis and azotemia are rarely relieved by the infusion of hypertonic saline solutions (200—300 ml of a 5 per cent sodium chloride solution) since irreversible intracellular changes appear The outcome is usually fatal The syndrome occasionally appears in cardiacs without ascertainable reason (movement of electrolytes? abnormal water retention? action of aldosterone?)

(2) HYPOCHLOREMIC ALKALOSIS (low chloride syndrome) The excretion of chloride under the influence of an injection of mercury is excessive and may be greater than that of sodium When the chlorides fall below 86 mEq per liter no diuresis results from the injection A fall by only 4—6 mEq may be of

Ammonium chloride is necessary only if mercury alone does not suffice or if injections of mercury are repeated at short intervals and the danger of hypochloremia exists

If doses not larger than 2 ml are given intramuscularly at intervals of no less than four days no accident will be seen in the course of many thousands of injections apart from hypersensitivity Certainly the injections must be discontinued at once with evidence of colon irritation or stomatitis It is astonishing how well the injections are tolerated One of our patients received more than 700 injections in 14 years Such patients are often observed and receive their injections on every *fourth* or *fifth* day without any sign of renal irritation

The combination of a mercurial diuretic with decholin (5 ml) in the same syringe injected very slowly has been frequently recommended However unpleasant accidents caused by decholin have been observed

No examination gives us as clear a picture of the effect of our diuretic therapy as weighing the patient

Mode of Administration The customary method of administering mercurial diuretics was for many years by intravenous injection The injection must be properly performed Some patients are so sensitive that the small amount of the preparation on the needle to say nothing of a paravenous injection suffices to cause a severe necrosis of the skin that requires months to heal For this reason the needle through which the preparation is withdrawn from the ampule is never employed for the injection The preparations are injected only if one is absolutely sure that the injection is exclusively intravenous

Intramuscular injections are now the method of choice since dangerous hypersensitivity reactions can thus be avoided they usually do not hurt or are only slightly painful The original mercurial organic diuretic novasurol it may be recalled was for years given only intramuscularly none dared to essay intravenous injection Painful infiltration following intramuscular injection is avoided if 1 ml of a 1 per cent solution of procaine (or a similar preparation) is added to the mercurial preparation in the same syringe The addition of procaine not only prevents any immediate (though slight) pain but it prevents secondary inflammation and irritation (Freud and Meyer) The best site for the injection is located in the posterior axillary line three fingers below the crest of the ileum In obese patients the injection must be made with a needle of sufficient length if this precaution is not taken the injection may actually be subcutaneous or be made into the deep adipose tissue where it causes necrosis A true intramuscular injection never causes necrosis

All injections should be given early in the morning The diuresis follows the injection in two to three hours and for the most part is over by bedtime If the injection is given later during the day the night rest is disturbed The injection of mercurial diuretics into a pleural effusion or into ascitic fluid is dangerous and may lead to serious local irritation Marked diuresis may follow such injections but they possess no advantage The appearance of a profuse diuresis following an intra

peritoneal injection (done only in the presence of ascites) begins within a few hours and rarely exceeds two days This proves that ascitic fluid is quickly absorbed and reformed otherwise the rapid action of the injection would be incomprehensible

Suppositories of mercupurin or those made from some other organic mercurial diuretic produce a considerable diuretic effect (Dennig and Krause) They should be inserted after a cleansing enema The suppository should be covered with pantocaine or nupercaine ointment Fissures and hemorrhoids are a contraindication Since some suppositories contain a rather large amount of the active ingredient they should not be given more often than every four days Many times the suppositories cause diuresis only after preliminary preparation with ammonium chloride When the administration of injections is impossible for some reason suppositories may be tried

The oral administration of the organic mercurial diuretics was tried early (Saxl) and has been recommended repeatedly If 2 to 3 tablets are given daily some diuresis may be obtained Often evidence of intoxication develops and in one series of 39 cases toxic effects appeared in 14 This also holds for preparations introduced recently and declared nontoxic Orally administered mercury is often excreted days after its ingestion and cumulative effects are common

Ammonium chloride nitrate and sulfate if given in sufficient doses may alone provoke a moderate diuresis and increase the diuretic effect of the mercurials In the body the ammonium ions are synthetized to urea and the acid radical remains Ammonium chloride is preferred because methemoglobinemia has followed the employment of ammonium nitrate The mode of action is not entirely clear Presumably acidification may help to liberate mercury in the renal tubuli The administration of an acidifying diet also increases the water and sodium chloride diuresis caused by theocin (theophylline) A similar purpose is served by the administration of 20 ml of dilute hydrochloric acid in 500 ml of water

Large doses of ammonium chloride are recommended We advise 6 Gm ammonium chloride in enteric coated tablets (i e 6 tablets of 1 0 Gm) daily for two days before and 3 Gm on the day the injection is given Others suggest smaller doses for instance 2 Gm of ammonium chloride two hours before the mercurial diuretic is injected Untoward effects (gastric irritation) are rare with enteric coated tablets In many cases ammonium chloride is unnecessary since the mercurial injection alone affords a satisfactory result There is no justification for administering ammonium chloride daily for a long time prescribed in this manner it loses its diuretic action and causes acidosis

Diomax — Diuril

A mild diuretic effect of sulfonamides has been known for a long time and one synthetic preparation Diomax with a new organic structure (acetazole amide) has a marked diuretic action with very few side effects

Ammonium chloride is necessary *only if* mercury alone does not suffice or if injections of mercury are repeated at short intervals and the danger of hypochloremia exists

If doses not larger than 2 ml are *given* intramuscularly at intervals of no less than four days *no accident* will be seen in the course of many thousands of injections apart *from* hypersensitivity Certainly the injections must be discontinued *at once* with evidence *of colon* irritation or stomatitis It is astonishing how well the *injections* are tolerated One of our patients received more than 700 *injections* in 14 years Such patients are often observed and receive their *injections* on every fourth or *fifth day* without any sign of renal irritation

The combination of a mercurial diuretic with decholin (5 ml) in the same syringe injected very *slowly* has been *frequently* recommended However unpleasant accidents caused by decholin have *been observed*

No examination gives us as clear a picture of the effect of our diuretic therapy as weighing the *patient*

Mode of Administration The customary method of administering mercurial diuretics was for many years by intravenous injection The injection must be properly *performed* Some patients are so sensitive that the small amount of the preparation *on the needle* to say *nothing of a* paravenous injection suffices to cause a severe *necrosis of the* skin that requires months to heal For this reason the needle *through* which the preparation is withdrawn from the ampule is *never* employed for the injection The preparations are injected only if one is *absolutely sure* that the *injection is exclusively* intravenous

Intramuscular *injections* are now the method of choice since dangerous hypersensitivity reactions can thus be avoided they usually do not hurt or are only slightly *painful* The original mercurial organic diuretic novasurol it may be *recalled* was for years *given only* intramuscularly none dared to essay intravenous injection *Painful* infiltration following intramuscular injection is avoided if 1 ml of a 1 *per cent* solution of procaine (or a similar preparation) is added to the *mercurial* preparation in the same syringe The addition of procaine not only prevents any *immediate* (though slight) pain but it prevents secondary inflammation and irritation (Freud and Meyer) The best site for the injection is located in the *posterior* axillary line three fingers below the crest of the ileum In *obese patients* the injection *must be made* with a needle of sufficient length if this precaution is *not taken* the injection may actually be subcutaneous or be made into the *deep* adipose tissue where it causes necrosis A true intramuscular injection never causes necrosis

All injections should be *given early* in the morning The diuresis follows the injection in two to *three* hours and for the most part is over by bedtime If the injection is given *later* during the day the night rest is disturbed The injection of mercurial diuretics into a pleural effusion or into ascitic fluid is dangerous and may *lead to serious* local irritation Marked diuresis may follow such *injections* but they possess no advantage *The* appearance of a profuse diuresis following an intra

the hydrogen cycle and 20 per cent in the potassium cycle Finally Katonium up to 75per cent an ammonium and 25per cent a potassium resin is given in doses of 15 grams three times daily

The resins also seem to absorb riboflavin and thiamin Since the absorption of potassium may lead to a dangerous hypokalemia one third of the resin is in the potassium cycle so that potassium ions are available for reabsorption Intake of resins can also cause hyperchloremic acidosis because hydrogen ions are released and basic ions lost in the feces chlorides are not removed by the usual resins Therefore a large percentage of the resins are in the ammonium cycle and are able to release the ammonium in the gastrointestinal tract

In vitro 1 gram of resin removes approximately 10 mEq of sodium but in vivo the amount depends upon the intake of sodium and on other factors

The acidosis is partly compensated by ammonia formation and the excretion of more carbon dioxide via the lungs The acid urine may cause albuminuria and casts to appear

While resins can be prescribed with reasonable safety they should never be administered in the home continuous control of the sodium chloride potassium blood levels as well as of NPN and carbon dioxide combining power are needed With the increase of chloride in the blood and a decrease of bicarbonate plasma concentration there is great danger of a high NPN Prolonged administration resulting in the removal of calcium may lead to bone demineralization With removal of potassium digitalis toxicity appears in patients taking this drug and dangerous arrhythmias occur Rarely fecal impaction occurs

Whenever loss of appetite weakness or vomiting appear therapy should be discontinued and one should check the blood for the substances mentioned above

The granulated resins are best taken with cream as in a cereal the powdered forms with orange or other fruit juices which also serve to supply potassium.

The indications are few While diet may be more liberal and may contain more salt few people like the resins which taste like sand and which they must ingest only in order to get more of the food they desire In patients who are sensitive to mercury that is to all mercurial diuretics the resins may save or prolong life It should be stressed however that even if resins are taken the diet can never be really liberal

Renal damage is an absolute contraindication Many refuse the resins because of diarrhea or constipation vomiting nausea or loss of appetite

Southey Tubes

When all diuretics fail and tense edema is present drainage with Southey tubes is necessary This represents a last resort since the danger of secondary infection and the development of erysipelas is great Fortunately this procedure has rarely been necessary since the introduction of the mercurial diuretics But there are times when tubes must be employed because all other therapy is fruitless

We have seen patients who responded to ordinary diuretics well only after the successful employment of the Southey tubes and then were kept free from edema for years

TREATMENT OF CHEYNE STOKES RESPIRATION

Cheyne Stokes breathing and the various forms of paroxysmal nocturnal dyspnea which result from cardiac failure (left ventricular failure) represent indications for digitalis therapy However some time elapses before digitalis helps unless the rapidly acting pure glycosides or strophanthin are given Furthermore not every patient is relieved by digitalis and signs of failure may persist despite energetic digitalization Therefore it is often necessary to treat Cheyne Stokes respiration symptomatically

Oxygen Since an oxygen deficit and hyposensitivity of the centers have long been recognized as precipitating causes of Cheyne Stokes breathing frequently an effort has been made to obtain improvement by means of oxygen inhalation as well as by agents which stimulate the cerebral centers

As a matter of fact the inhalation of oxygen acts immediately and abolishes Cheyne Stokes in most cases only a few patients do not respond The apneic pauses vanish and respiration becomes regular Naturally improvement persists only as long as the administration of oxygen is continued

Inhalation of oxygen by nasal catheters is useful and may tide the patient over distressing periods The great anxiety and restlessness of the patient with a severe form of Cheyne Stokes often interferes with their use and makes the employment of oxygen masks also impossible The oxygen tent is superior and may quickly abolish periodic breathing as well as the mental confusion and restlessness combined with it

Central Stimulants All attempts to influence Cheyne Stokes respiration by the administration of central nervous system stimulants have failed Lobeline strychnine atropine and coramine as well as caffeine are useless for this purpose

Aminophylline (Theophylline with ethylenediamine) which is also known as metaphylline euphylline has an almost specific action This compound was used for many years as a diuretic and vasodilator while its excellent effect on patients with Cheyne Stokes breathing was only occasionally mentioned until this action was stressed by Vogl The relief afforded by the preparation is so great that the term miraculous is often used by patients and even by the physician in charge

A few minutes following the injection the periodic alternation of dyspnea and apnea disappears and the respiration becomes regular With this the restlessness and anxiety subside and patients who have not had a good night for weeks sleep quietly It acts like magic The patient is not compelled to sit up nor to pace the room restlessly but lies quietly in bed seeming and feeling altogether like a different person

The most effective method of administering the preparation in patients with Cheyne Stokes is the intravenous injection An ampoule containing 0 24 Gm of aminophylline is injected very slowly A rapid injection leads to marked va o

dilatation and flushing with the sensation of warmth not unlike the sensation following an intravenous injection of a calcium or quinine preparation In the patient suffering from a cardiovascular disorder too rapid an injection may be followed by vertigo marked fall of blood pressure and even a mild collapse Therefore the aminophylline should be diluted with saline or a 5 per cent solution of glucose and injected so slowly that the injection requires at least 5 minutes If this method is followed no harm need be feared It is best to give the injection during the evening since Cheyne Stokes respiration tends to occur or to become worse at night If necessary an injection can be given twice in 24 hours Hyper sensitivity to aminophylline (headache vomiting) is rare This treatment may be continued for a long time the mere fact that the preparation is employed over a considerable period is in itself no reason for stopping it

Intramuscular injections are not recommended because they often cause pain Occasionally however an intramuscular injection is well tolerated perhap due to a better balance of the hydrogen ion concentration The dose for intramuscular injections may be the same or a double amount (0 48 Gm) Almost as effective as an intravenous injection is a retention enema An ampoule containing 0 48 Gm or a corresponding amount of aminophylline powder (0 5 Gm) is diluted with about 30 ml of tap water and given as a retention enema Similar but a little less effective is the administration of aminophylline in a suppository containing 0 5 Gm The administration of aminophylline as a suppository results in satisfactory levels of theophylline in the blood plasma (Glass et al) One suppository is given at bed time and another during the day if necessary Aminophylline tablets have little value in Cheyne Stokes breathing

The mode of action of aminophylline is still obscure Aminophylline is a vasodilator but this effect is hardly responsible for the improvement since stronger vasodilators like the nitrites and even large doses of nitroglycerin are not effective in Cheyne Stokes respiration Theophylline like all xanthine bodies is a central stimulant But other central stimulants even though stronger like caffeine do not influence Cheyne Stokes breathing We are dealing therefore with a specific effect of the preparation It has been maintained that other theophylline preparations for example theophylline with sodium acetate have no effect on periodic breathing while ethylene diamine and some other amines influence the breathing like aminophylline According to our observations however intravenous injections of theophylline sodium acetate act favorably on Cheyne Stokes respiration and we have seen equally good effects when urea was used as a solvent for the theophylline instead of ethylene diamine The explanation of the action of aminophylline in Cheyne Stokes is made more difficult by the recent discovery (Kety) that after injection of this compound the cerebral blood flow is decreased and not increased

Not rarely the patient reports in the morning after having had an evening dose of aminophylline that the night could have been a good one since breathing was much easier than it had been for a long time but he was unable to sleep This is due to the central stimulation by theophylline which may cause consider

able excitement in some patients Therefore the combination of a sedative with aminophylline is often necessary A barbiturate will usually offset the stimulating effect of aminophylline

Morphine and Sedatives Morphine particularly in the form of an injection of 0 01 Gm or more is contraindicated in Cheyne Stokes breathing In fact even in healthy persons morphine causes Cheyne Stokes which in turn also responds well to aminophylline

A useful sedative for cardiac patients although it has been unjustly avoided for many years is chloral hydrate The doses which depress the circulation are much larger than those customarily employed as a sedative and hypnotic Doses of 2 Gm per rectum or smaller amounts in the form of a syrup by mouth are effective and harmless

CARDIAC ASTHMA AND PULMONARY EDEMA

Cardiac asthma and acute pulmonary edema (paroxysmal nocturnal dyspnea) also result from left ventricular failure and patients presenting these phenomena require digitalis Specific therapy is however necessary during the attacks and in order to prevent recurrences until digitalis brings about the desired effect

Morphine The sovereign remedy in these attacks is morphine If given quickly and in sufficient doses it affords immediate relief While the finer mechanism of its action is still unknown one can assume that it helps by di minishing the excitability of the centers

No stimulating effect of morphine on the circulation is known and morphine certainly does not help to relieve an attack of paroxysmal nocturnal dyspnea by improving the circulation Its prompt effect has always given support to those theories of paroxysmal nocturnal dyspnea which assumed abnormal reflexe or an abnormal condition of the respiratory centers as the causal mechanism

Morphine sulphate is usually given hypodermically during the attack and the dose should not be less than 0 02 Gm Since quick action is necessary and absorption from the cold skin and from the subcutaneous tissue may be slow it is better to administer morphine in this dosage intramuscularly Even the intravenous administration of 0 01 Gm of morphine sulphate has been recommend ed It is well to include atropine sulphate in the amount of 0 0005 Gm (½ mg) with the injection of morphine

Morphine also prevents recurrences of the attacks Very small doses suffice to guarantee a quiet night and prevent new attacks of cardiac asthma and pul monary edema An injection of 0 01 Gm of morphine or pantopon or even one tablet or 0 02 Gm of pantopon is given at bed time The most inexpensive method of administration particularly in hospitals is by an aqueous solution of morphine hydrochloride or sulphate The administration of 20—30 drops of a 1 per cent solution usually suffices It has the advantage of rarely causing morphinism at least we have never observed it in many hundreds of cases After a few days the use of morphine usually becomes unnecessary because car diac action has been improved by digitalis

the consequently increased return of blood to the heart is considered one of the major reasons for the nocturnal appearance of the attacks With the legs dangling the circulating blood volume may be reduced by 400 ml Patients in shock however should lie flat or even with the lower part of the body elevated

Aminophylline Aminophylline has also been recommended for the attacks of cardiac asthma There is no doubt that in the absence of pulmonary edema when expiration is prolonged and difficult when a great deal of bronchospasm exists aminophylline may be useful

Atropine Doses of 1—2 milligrams of atropine have also been recommended for decreasing reflex action and preventing secretion This treatment is useful in experimental pulmonary edema One must however be careful in the intravenous administration of large doses of atropine to patients with coronary sclerosis because the increase of heart rate may cause cardiac hypoxia and may have serious consequences For this reason and owing to the disagreeable side effects of large doses of atropine this treatment is not recommended

Hypertonic Glucose Solution Very effective is an injection of a highly concentrated solution of dextrose for example 40 ml of a 40—50 per cent solution The improvement may appear within a few minutes The action is not ascribed to the sugar A purely osmotic effect of the hypertonic solution is responsible

Intravenous injections of sugar with or without insulin have frequently been recommended for the treatment of various heart ailments These injections were supposed to act particularly well in various myocardial and coronary diseases No proof has been advanced as yet of any beneficial effect The introduction of hypertonic solutions into the circulation causes an appreciable increase of the circulating blood volume by withdrawing fluids from the tissues and augments the load for the heart In patients with cerebral edema an increase of the spinal fluid pressure has been observed after an initial fall Therefore the administration of 50 per cent sucrose has been recommended for these cases The cerebrospinal fluid barrier is not permeable for sucrose Hypertonic solutions of sucrose have however an injurious effect on the kidneys

Even if one employs venesection tourniquets or hypertonic glucose solutions no time should be lost in giving morphine as soon as possible This treatment alone is reliable only in the terminal pulmonary edema is it useless

Morphine in Cardiac and in Pulmonary Dyspnea

It was mentioned in the preceding section that morphine is a most effective remedy for cardiac asthma and pulmonary edema It is no less useful in other forms of cardiac dyspnea

For decades morphine was hailed as a second digitalis and was employed very often in cardiac patients At present its beneficial effects on decompensated and dyspneic cardiac patients is often forgotten

In the chapter on dyspnea it was shown that even the form of breathlessness due to pulmonary congestion does not depend exclusively upon the mechanical

effects of congestion but that various reflexes play an important role In this group of patients examination of the arterial blood reveals no hypoxia As long as no pulmonary complications exist the blood is normally saturated with oxygen and contains even less carbon dioxide than normal blood Pulmonary congestion produces reflex hyperventilation This hyperventilation alone may exhaust the patient because the greater physical work of respiration represents an increased burden It also leads to the detrimental effects of excessive exhalation of carbon dioxide (hypocapnia) If small doses of morphine are given to such patients for instance 20 drops of a 1 per cent solution of morphine sulphate in water and the irritability of the centers is reduced slightly the dyspnea diminishes markedly and with it the added work imposed on the circulation Following one dose of morphine to an otherwise untreated patient one can often observe that in addition to the great subjective relief a profuse diuresis may start and the size of the liver may diminish The great restlessness of these patients is abolished and they can be handled much easier The statement of clinicians about 50 years ago namely that compensation may be achieved with morphine alone is certainly true for some decompensated non fibrillating patients

Therefore every decompensated dyspneic cardiac patient should receive small doses of morphine in the morning and evening for the first few days of treatment until the beginning of the digitalis effect makes this treatment unnecessary The small doses recommended do not inhibit diuresis and no danger of morphinism need be feared if these doses are given by mouth for the short time they are indicated

At this occasion it is appropriate to stress the fact that in contrast to cardiac dyspnea all types of pulmonary dyspnea contraindicate the use of morphine In these cases oxygen saturation of the blood is diminished and carbon dioxide retention may also take place due to the pulmonary lesion In this instance the *dyspnea is not the abnormal outcome of various factors connected with decom*pensation but an important phenomenon necessary to maintain life and to compensate for the pulmonary lesion Once the irritability of the respiratory centers is reduced by morphine and the respiration is slowed the exchange of gases suffers and hypoxia with increased cyanosis and hypercapnia appear Patients soon fall asleep the breathing becomes more infrequent longer and longer respiratory pauses appear cyanosis increases and soon death may occur by respiratory standstill

This is not a rare event and such occurrences unfortunately are encountered all *too frequently Often* the connection between the administration of morphine and the death of the patient is not clear to the physician he attributes the fatality to the severe pulmonary process It is regrettable that most of the current textbooks of clinical medicine and even of pharmacology do not stress this contraindication

Morphine must be used with greatest care in cases of severe emphysema and kyphoscoliosis in diffuse bronchopneumonia in bronchial asthma in bilateral

tuberculosis and pneumonia and in diffuse metastatic pulmonary neoplasms In mild emphysema bronchopneumonia tuberculosis or malignancy of the lung morphine may be administered if indicated however in those extensive pulmonary lesions which cause cyanosis or dyspnea morphine is forbidden We have seen patients die within a half hour with the picture just described because inexperienced physicians ordered morphine for severe pain in a patient with carcinoma and extensive pulmonary metastases or advanced pulmonary tuberculosis Patients with bronchial asthma rarely die during an untreated attack This happens however often if morphine is given If for any reason morphine must be administered or the physician is uncertain how much of the dyspnea is of pulmonary origin small doses of the drug or better demerol may be given The patient should be watched carefully so that the centrally acting stimulants like atropine coramine caffeine or aminophylline can be administered promptly if the depression of the respiration becomes more marked Nallin in the amount of 5 to 10 mg is effective

For the same reason in pulmonary edema when copious hemorrhagic sputum is already evident and bubbling rales are audible all over the lungs it is well to omit morphine because a mechanical impediment causes the dyspnea and its suppression may lead to asphyxia Morphine is given in these cases after one succeeds in causing the absorption of the alveolar transudate by an intravenous injection of hypertonic glucose solution or by the use of a high pressure oxygen mask

CARDIAC STIMULANTS

In patients with cardiac weakness preparations of the digitalis or strophanthin group are primarily indicated In some cases for instance in acute cardiac failure of various origins in acute pulmonary edema in pulmonary embolism and right heart failure one may find it necessary to stimulate cardiac action immediately before the digitalis glycosides can show an effect on the heart Sometimes side effects of digitalis like extrasystoles forbid continuation of digitalis even if it is otherwise indicated For this purpose a host of remedies have been recommended but only a few are really useful

Strychnine For many years strychnine was employed as a cardiac stimulant It was early recognized however that strychnine has no effect on the heart and can only be used to increase vascular tone It has been given by mouth or by subcutaneous injection in the dose of 2 mg three or four times daily

Pressor Amines Epinephrine has a very strong action on the circulation It combines a positive inotropic action on the heart muscle with a constrictor effect on the vessels in wide areas of the body Nevertheless its disadvantages are great When given by mouth or by rectum it is practically inert If administered hypodermically its action is sometimes stormy and vanishes in a short time Even small doses are dangerous to cardiac patients due to the resultant marked tachycardia the elevation of blood pressure and the remarkable increase of the oxygen requirements of the myocardium which often cannot be

met Therefore this drug should never be used in cardiac patients even if it seems necessary for other purposes for instance as an addition to a local anesthetic or for the treatment of swollen nasal mucous membranes

Some of the newer pressor amines and substances related to adrenalin however are indicated in cases in which for instance in myocardial infarction during local anesthesia or following sympathectomy the blood pressure threatens to fall to dangerously low levels Paredrine and neosynephrine are given in these cases without undue danger to the heart A single dose of 2 mg of paredrine by mouth or 5—10 mg of paredrine or neosynephrine by intramuscular injection may be used Isuprel (10 mg) may be given sublingually

The action of these drugs is more prolonged and less stormy than that of epinephrine

Camphor Coramine Metrazol Preparations of camphor were greatly cherished by many physicians in various countries as cardiac remedies and were given whenever stimulation of the heart seemed indicated There is however no evidence available to prove a stimulating action of camphor on the heart The same holds for some synthetic preparations which were originally recommended as synthetic camphor like stimulants The best known of these preparations are coramine and metrazol (cardiazol) These preparations have no stimulating cardiac effect nor do they increase contractility of the heart They stimulate medullary centers and only in this way lead to a moderate rise of blood pressure and increased respiration They should not be employed for stimulation of the heart muscle

Xanthine Bodies Several preparations belonging to the xanthine group possess a stimulating effect on the heart They are particularly useful because this effect is combined with vasodilatation and some diuretic action

It has been pointed out before that some of the xanthines like theophylline stimulate the heart muscle Caffeine in particular increases the contractility of the myocardium and increases the amplitude of contraction especially of the damaged or weakened heart The effect on the heart rate varies because this depends on various central and peripheral factors which act in opposite directions

For injection the soluble double salts like caffeine and sodium benzoate are used A subcutaneous injection of 0 25—0 3 Gm may be given every two hours when necessary For oral treatment caffeine purum in doses of 0 1 Gm is useful However strong black coffee which the patient may take much more willingly is no less effective than a capsule or an injection of caffeine The caffeine content of a small cup of coffee may exceed the amount given in a capsule or injection

VENESECTION LEECHES

The effect of venesection on cardiac asthma pulmonary edema and in hypertension was discussed in the corresponding chapters This therapeutic procedure is time honored and purely empirical

Patients with marked venous stasis and hepatic engorgement that is patients with right heart failure seem to derive some benefit from phlebotomy

The removal of 400—500 ml of blood may bring relief The venous pressure may fall temporarily and the patient may improve subjectively The *spinal fluid* pressure also falls (Robertson and Fetter) Usually however a delay of several hours is safe and the same result can be secured by an injection of a mercurial diuretic

In patients with right heart failure in the course of pulmonary disease (decompensated cor pulmonale) phlebotomy sometimes affords excellent results In general however this procedure is rarely necessary and rarely used Simultaneously with a lowering of right atrial pressure venesection causes an increase of cardiac output This may be due to the fact that the heart was over loaded before the phlebotomy and the extreme increase of filling pressure had led to a fall in output

It has been pointed out that phlebotomy is helpful in polycythemia complicating pulmonary vascular sclerosis or congenital heart lesions It helps in plethoric patients with chronic congestive heart failure

When the use of leeches is recommended one often encounters a smile of pity We are however able to confirm the observations of others (Sir Thomas Lewis) that this old method of treatment may be very useful if employed upon definite indications The most important situation in which leeches may bring relief is in patients with an acute engorgement of the liver leading to severe pain *in the right hypochondrium* Under these circumstances the application of three or four leeches over the liver suffices to bring relief in a few hours A demonstrable reduction of the size of the liver may be found afterward Although patients object at first to the use of these unpleasant creatures they report definite relief in every instance when the procedure is employed Nothing definite is known about the modus operandi of this measure It has been suggested that the success may be due to the relation of some vascular spasm within the liver via a cutaneous visceral reflex We found however that irritation of the corresponding section of the skin by cantharides plasters or cupping decidedly less effective

TOTAL THYROIDECTOMY AND OTHER OPERATIONS IN CARDIAC FAILURE

Total thyroidectomy in patients with intractable angina pectoris has been discussed

It has been known for more than 30 years that subtotal thyroidectomy can exert an excellent effect in patients with organic heart disease and mild hyper thyroidism In these patients the signs of decompensation may vanish soon after the operation sometimes the heart even becomes smaller disturbances *of rhythm* disappear and the functional capacity of the patient increases remarkably The postoperative improvement is very impressive since previously intensive therapy with the most powerful agents available often had failed

The occasional observation of similar striking improvement in patients operated on for an assumed hyperthyroidism although subsequent histologic examination of the thyroid revealed no sign of hyperfunction suggested subtotal

thyroidectomy also for cardiac patients without hyperthyroidism (Blumgart Levine) Since the initial improvement in several cases was followed soon by a recurrence of the original symptoms it was recommended that subtotal thyroidectomy should be discarded and that *total* thyroidectomy be performed The recurrence of symptoms after the older procedure was attributed to regeneration of thyroid tissue

The operation was adopted by many physicians with enthusiasm Others repudiated it At the present time it seems to be rarely employed since thyreoidectomy can be accomplished by drugs without surgery

The procedure deserves consideration in a very carefully observed case if in spite of intensive digitalis therapy the use of the modern diuretics and despite constant hospitalization a tolerable state of compensation cannot be maintained When prolonged observation shows that the myocardium of these patients is in good condition and in the absence of the contraindications to be mentioned presently the operation may be tried One should not treat by thyroidectomy a patient in whom decompensation is merely the result of an infection a pulmonary embolism or an arrhythmia In these instances removal of the cause of decompensation furnishes relief in a simpler way No signs of progression in aortitis should be present and no evidence of activity in cases of rheumatic heart lesion

At first the success of the procedure was ascribed to the fall of the basal metabolic rate It was believed that the operation leads to a diminished oxygen requirement in the tissues and thus the demands of the tissues are adapted to the impaired circulation But it soon became clear that the improvement appears before the basal metabolism is lowered indeed occasionally it was evident a few days following the operation Therefore abolition of a direct thyroid effect on the circulation is involved When the basal metabolic rate falls to low levels and evidence of hypothyroidism appears small doses of thyroid are given Sometimes we were able to maintain the basal metabolic rate at a normal level in these patients while the improvement of the circulation remained

One must also consider that fact that with the development of myxedema the cardiac output as well as circulation time fall to lower levels This too forces us to seek for another explanation for the benefit of surgical or chemical thyroidectomy than simply the diminution of the oxygen requirements of the tissues

Another indication for this mode of therapy are patients with paroxysmal tachycardia or paroxysmal flutter and fibrillation who suffer from very frequent attacks and who do not respond to the usual therapy Here diminution of thyroid activity may lessen the severity and incidence of the attacks

Thiourea derivatives proved helpful and were used with advantage in patients with congestive heart failure as well as in patients with angina pectoris However the simplest and for the patient least inconvenient therapy is that with radioiodine The iodine uptake is at first determined with a tracer dose of I^{131} Then doses of 20—30 millicuries are given orally in intervals of 5—6 weeks Often good results are obtained early after the first dose The development of a myxedematous state is by no means necessary

It is claimed that in congestive cardiac failure this therapy helps in about 50 per cent of the cases In angina pectoris excellent results were reported in one third of the cases and worthwhile results in another one third In the latter group we found chemical thyroidectomy particularly helpful in patients with aortic stenosis and aortic insufficiency and decubital angina Recently Blumgart et al reported worthwhile improvement in 75 per cent of patients with angina pectoris and about 60 per cent of patients with congestive heart failure

Other Operations in Congestive Heart Failure

In patients with congestive cardiac failure particularly in mitral lesions Cossio recommended ligation of the inferior vena cava Satisfactory results were reported by him and others (Bernath et al) The operation is contraindicated in high output failure but provided immediate relief in the congestive heart failure of mitral patients

These operations as well as the creation of an artificial experimental tricuspid insufficiency (Cossio et al) are now superseded by direct operation on the cardiac valves

ANTICOAGULANTS IN CONGESTIVE HEART FAILURE

Thromboembolism in patients with congestive heart failure is a common complication and about one third of patients with rheumatic valvular lesions develop heart failure because of pulmonary emboli If — as usually happens — the patient is forced to stay in bed the danger of new embolism is even greater

The thrombi are not only located in the lower extremities but also and even more extensively in the venous plexusses of the pelvis the hypogastric veins the prostatic and ovarian plexusses which we had examined for years in every post mortem examination of patients dying from congestive heart failure and which we found thrombosed in practically every instance

Such pulmonary embolisms coming repeatedly over a prolonged period may by themselves cause heart failure and are detrimental for patients whose hearts are already overburdened because of rheumatic fever or coronary sclerosis

It has often been stated that therapy with digitalis increases the danger of thrombus formation In a careful study of this question Cormsen found no correlation with the degree of diuresis and thrombosis but a good correlation between intensity of therapy and thrombosis

For these reasons prolonged anti coagulant therapy has been recommended in patients with congestive heart failure (Wishart and Chapman Harvey and Finch) and a significant reduction of the occurrence of thromboembolism has been reported Griffith et al found in the treated group an incidence of this complication of 1 8 per cent while it was 15 5 per cent in the untreated group

A final decision on whether or not the measure should be used routinely is not yet possible One will understand that by the use of anticoagulants new hazards are added to those already existing It should appear advisable to wait until

studies covering a large amount of material show that the dangers of the therapy are minor and the advantages outweigh them

DIETARY QUESTIONS

Even if no special diet is required detailed instructions should be given to cardiac patients since the definite advice is always welcome

Compensated cardiac patients in general need not be subjected to great dietary restrictions A normal mixed diet is permissible Foodstuffs which cause flatulence foods which are not easily digested and large meals should be avoided Eat frequently but do not take too much at one time is an excellent precept Fluids should be taken mainly between meals

The dietary requirements in patients with hypertension coronary sclerosis or myocardial infarction have been discussed in the chapters dealing with these conditions

Patients with cardiac failure and edema should receive a diet poor in salt or even salt free Even healthy persons who receive a salt free diet for one day have a profuse diuresis and show a loss of weight surpassing 1 Kg within 24 hours The great contribution of such a diet to the development of a satisfactory diuresis in edematous patients is readily understandable

Recently a high fluid intake has been recommended in cardiac edema (Schemm) It was pointed out that edematous patients may even be dehydrated If the sodium in the diet is restricted and the diet yields a neutral or acid ash remarkable diuresis may be obtained even with administration of more than 4 000 ml of water daily Meat eggs cereal prunes and plums belong to the food stuffs giving an acid ash Milk fruit juices and fruit with the exception of those mentioned above should be avoided Ammonium chloride (3 Gm daily) or a few drops of dilute hydrochloric acid in every glass of water serve to increase the acidity This diet has been abandoned by us and in many other places

The Karell diet consisting of 800—1 000 ml of milk only taken during the day is very satisfactory The use of milk has however some disadvantages Many patients do not like it in many it causes meteorism and distension and in others diarrhea Moreover milk is salt poor and not salt free It contains 750 mg of sodium per liter For this reason raw or cooked vegetables may be substituted for milk All varieties of fruits or vegetables are permissible Even potatoes are allowed particularly for heavy eaters They may be eaten with the skin which on account of their high content of potassium are supposed to exert some diuretic effect The total quantity of fruit or vegetables permitted during 24 hours should not exceed 1 200 Gm No other food and no other drinks are given This diet is followed for three days in succession and then supplemented by proteins

Artificial salts have been devised but most of them have a high content of sodium and are therefore of little value Usually one can dispense with them Garlic pepper paprika vinegar and the like are permitted

In patients who develop marked albuminuria a hypoproteinemia may appear during chronic congestion Therefore a diet rich in proteins is necessary

In patients who are overweight a low caloric intake will be prescribed For most patient 20 calories for one Kg body weight are suggested The calculated ideal weight of the patient rather than the actual weight should serve as a basis for the dietary regime

The amount of liquid permitted to a patient with decompensation should not exceed 800—1 000 ml within 24 hours Naturally fruits vegetables soups are calculated as fluids

Excessive smoking and consumption of large quantities of alcohol are prohibited It has been stressed in the appropriate chapters that in patients with hypertension with coronary diseases and particularly in patients with peripheral vascular diseases smoking is harmful even in smallest quantities while alcohol taken in moderation is useful

AIR TRAVEL CLIMATE

In this era of air travel the question must often be decided whether the patient may undertake a trip by plane With the exception of obvious contraindications such as severe congestive heart failure or a fresh myocardial infarction the answer will most often be yes The small risk is illustrated by the experience (Graybiel) that among 7 million passengers carried by five major airlines only 3 deaths occurred during flight and 5 shortly after landing from cardiovascular disease The rule if you can walk you can fly was accepted but consideration should be given to certain facts

A patient with a myocardial infarction should not fly until four months have elapsed since the day the infarction occurred Dyspneic patients should not fly Among laymen the opinion prevails that pressurized planes are safe however they are pressurized at a level of 7 000—8 000 feet Some patients with angina pectoris need oxygen at 5 000 feet Patients with status anginosus or attacks of angina pectoris at rest (angina de decubitus) should not fly Abdominal distention due to the expansion of abdominal gases often causes discomfort The administration of 1 tablet of dramamine every four hours is recommended

Cardiac patients particularly those with congestive heart failure do not tolerate humid and hot climate well On the other hand even in a subtropical climate patients with angina on effort are more comfortable and the need for nitroglycerin diminishes

The literature on observations on the occurrence of attacks of coronary thrombosis or apoplexy in connection with particular barometric pressures and other climatic factors is large In Dallas Texas the incidence of myocardial infarction during the summer months is greater (Heyer et al) while the incidence in Northern cities seems to be greater in the winter Others reached different conclusions (Schnur) A sudden elevation of atmospheric temperature and humidity may precipitate an attack of left ventricular failure

emesis gastric lavage and purgation The efficacy of these measures depends upon the site and rapidity of absorption of the poison and the interval between ingestion and attempted removal Such variables as the delayed gastric emptying produced by shock or pylorospasm make it worthwhile to attempt removal in the absence of a contraindication Since prompt removal is essential it is more important to proceed with the means at hand than to wait for special equipment or solutions

Spontaneous *emesis* frequently follows the ingestion of irritants Vomiting may be induced by stimulating the pharynx the administration of gastric irritants (hypertonic saline solution mustard) or by the use of centrally acting emetic drugs such as apomorphine These measures however are often ineffective or contraindicated When patients are stuporous and gagging emetic drugs are usually ineffective and the administration of large amounts of fluid may hasten passage of the poison through the pylorus before vomiting occurs Whenever possible it is better to rely upon gastric lavage than the vagaries of emesis

Gastric lavage is associated with certain dangers It should not be attempted after the ingestion of strong acids or alkalies because of the danger of perforating the injured tissues Clinical judgment must be used in deciding whether the advantages of lavage outweigh its dangers as a stimulus when the patient is convulsing The danger of aspiration can be minimized by positioning the patient with head and shoulders down and the head turned to one side Careful removal of gastric contents in itself reduces the risk of aspiration in the unconscious patient The orogastric tube should be of sufficient size (30 to 40 French) to permit aspiration of particulate matter Passage into the esophagus is facilitated by flexing the patient s neck After the initial aspiration small amounts (in the range of 250 ml) of the lavage solution should be alternately instilled and aspirated The use of larger volumes increases the risk of forcing gastric contents through the pylorus Lukewarm water is a satisfactory irrigating liquid *Universal antidote* (e g activated charcoal 2 parts tannic acid 1 part magnesium oxide 1 part *water 100 parts) may have some* advantages but time should not be lost in its preparation if it is not immediately available In some poisonings lavage with a substance which destroys precipitates dissolves or neutralizes the poison may be of help These agents will be mentioned in the discussion of specific poisons

Following removal of poison from the upper gastrointestinal tract *cathartics* may be used to hasten the passage of the remaining poison out of the lower gastrointestinal tract Saline cathartics such as magnesium sulfate in amounts of 15 to 30 Gm may be left in the stomach following lavage Cathartics in general are contraindicated in strong acid and alkali poisoning

Prevention of Absorption of Topically Applied Poisons Removal of contaminated clothing should be followed by copious flooding of the involved area of skin or mucous membrane with water While organic solvents weak acids or bases may be more effective in certain instances (which will be noted) skin decontamination with water should proceed while they are being obtained Wiping must be gentle to prevent inunction of poison remaining on the skin surface If exposure is limited to an extremity venous occlusion with a tourniquet may be helpful in delaying systemic absorption

Prevention of Absorption of Injected Poison Cruciate incision and suction will remove unabsorbed poison which has been injected but this procedure is rarely feasible except in poisonous bites Absorption can be delayed effectively by the application of cold and tourniquets and by immobilization

Prevention of Absorption of Inhaled Poison Further absorption of toxic gases vapors aerosols and dusts can be prevented by removal of the victim to an uncontaminated atmosphere and by assuring adequate pulmonary ventilation If the casualty cannot be moved a protective mask should be applied

Symptomatic and Supportive Therapy For many poisons no specific antidote is known Therapy must then be directed toward control of manifestations as they appear Even in instances where specific antidotes are available such problems as hypotension and hypoxia must be attacked directly Certain of these manifestations appear with sufficient frequency to justify their brief discussion here

While *coma* is an ominous sign unresponsiveness rarely requires specific therapy per se Concomitant depression of respiratory and vasopressor centers however frequently requires prompt and vigorous treatment if the patient is to survive The comatose patient requires careful observation and meticulous nursing care (p 1770)

Hypotension may arise from any of a number of causes—anoxia depression of the vasopressor centers *autonomic ganglionic blockade loss of blood* water or electrolytes cardiac arrhythmia or myocardial damage Rational therapy is predicated upon correction of the underlying defect Vasopressor amines particularly norepinephrine are helpful in combating the shock produced by central depression and ganglionic blockade In the latter instance the patient is unusually sensitive to vasopressor amines For further discussion of the management of shock see p 1769

Tissue *hypoxia* also may result from varied causes poor pulmonary ventilation secondary to central respiratory depression muscular paralysis

bronchospasm retained secretions or upper airway obstruction impairment of alveolar capillary diffusion due to pulmonary edema deficient oxygen transport as in anemia methemoglobinemia carboxyhemoglobinemia shock and inhibition of cellular oxidation *When the hypoxia is produced* by underventilation the first step is to ensure a patent airway Secretions should be removed by suctioning and any obstruction relieved by the insertion of an oropharyngeal airway endotracheal tube or tracheotomy tube depending upon the site of obstruction If ventilation remains inadequate *despite a clear airway* and oxygen administration or if there is respiratory arrest the patient must be assisted manually or by mechanical means

Pulmonary edema produced by injury to alveoli exposed to irritant gases is less responsive to treatment than the pulmonary edema associated with cardiac failure (p 1307) Therapeutic measures include *suppression* of cough frequent suctioning high concentrations of oxygen under positive pressure aerosols of surface active agents adrenal cortical steroids bronchodilators and if infection complicates the picture antibiotics

The management of *methemoglobinemia* carboxyhemoglobinemia and inhibition of cellular oxidation will be discussed under the specific poisons producing these changes

Convulsions may be produced by a wide variety of poisons The management of seizures is discussed beginning on p 335

Electrolyte imbalance and *dehydration* are frequent sequelae to protracted vomiting and diarrhea In addition to these certain poisons produce more specific defects for example the acidosis of methanol poisoning and the hypocalcemia of fluoride poisoning *these will be described under the appropriate poison*

Acute hepatic insufficiency is the primary manifestation of some poisonings (chlorinated hydrocarbons cinchophen phosphorus and occasionally mushroom poisoning) and its management is described beginning on p 1504

Acute renal insufficiency may appear as a result of such prerenal factors as shock dehydration and electrolyte imbalance or as the result of concentration and excretion of nephrotoxic substances by the kidney When renal failure occurs it should be managed as outlined on p 1367

Cardiac arrhythmias produced by poisons are managed in a manner similar to those otherwise produced (p 1240)

SPECIFIC ANTIDOTAL TREATMENT

Specific antidotal agents fall into three categories First those antidotes which exert their therapeutic effect by *reducing the concentration of the toxic substance* by promoting excretion (e g the administration of chloride or mercurial diuretics in bromism) by combining cyanide with methemoglobin, lead with ethylene diaminetetraacetate or mercury with dimercaprol or by precipitation in the gut (e g the use of sulfate to precipitate certain alkaloids) Second there are antidotes which *compete biochemically* with the toxic substance for its receptor site (e g vitamin K_1 in coumarin poisoning or atropine in muscarine poisoning) Third are those antidotes whose pharmacologic action is antagonistic to that of the poison (e g picrotoxin in barbiturate poisoning) This last type of antidotal treatment merges with symptomatic therapy in many instances

CLINICAL MANIFESTATIONS OF SPECIFIC POISONINGS

In the discussions of specific toxic agents in this chapter many details of drug action have been omitted except where pertinent to the problem of recognition or treatment of poisoning Toxic manifestations due to drug hypersensitivity or allergy are *discussed elsewhere (p 1163) It has been necessary* to eliminate from consideration a large number of toxic materials to which exposure occurs only in specialized industrial procedures Instead emphasis has been placed on toxic agents which may be encountered by the general population In the references at the end of the chapter will be found further details of toxicologic and historic interest

Acetanilid Acetophenetidin Although symptoms resembling salicylate intoxication may follow overdosage of these agents the most prominent finding is methemoglobinemia with dusky cyanosis fatigue *and headache Treatment is symptomatic* (p 1198)

Acids Since strong mineral acids are not commonly found in the home ingestion is usually the result of suicidal attempt Necrosis sloughing bleeding and perforation of the gastrointestinal tract may be produced and chemical burns are usually visible in the mouth and oropharynx These lesions are more charred than the gelatinous burns produced by alkali and can often be differentiated from them by appearance alone Because of the danger of perforation lavage should not be attempted Treatment consists of dilution of the acid neutralization with weak alkali relief of pain and supportive measures if necessitated by shock or loss of blood and fluid Alkalies such as sodium bicarbonate which evolve carbon dioxide should be avoided *because of the possibility* of rupture of an eroded stomach Magnesium oxide or hydroxide and aluminum hydroxide are preferable If weak alkali is not immediately available the ingested acid should be diluted by administering water or milk

As with alkali burns delayed perforation or stricture formation may occur although the latter is said to be less common in acid burns

Aconite (Wolfsbane Monkshood Larkspur) Aconite is the active principle of several members of the larkspur family it is no longer used therapeutically because of its instability in solution Poisoning is usually due to ingestion of one of these plants and is manifested by vagal and peripheral sensory nerve stimulation and medullary depression Pathognomonic is intense tingling without erythema or evidence of inflammation This is followed by nausea vomiting abdominal pain diarrhea bradycardia hypotension visual impairment unconsciousness and death due to respiratory depression Treatment is purely supportive with large doses of atropine (0 5 to 1 0 mg) to counter the vagal effects

Alkali (Lye Drano Sodium Hydroxide, Caustic Potash Potassium Hydroxide, Washing Soda Sodium Carbonate, Potassium Carbonate Household Ammonia Ammonium Hydroxide) The caustic action of lye and other strong alkalies results in deep serious burns and subsequent scarring of the intestinal tract after ingestion The immediate effects of oral ingestion are redness and soreness of mouth and pharynx followed in several hours by sloughing of the mucosa and bleeding The same process occurs in the esophagus and stomach Treatment is directed toward cautious neutralization of the alkali with dilute acetic acid (10 per cent vinegar) Intubation during the acute stages should be avoided because of the likelihood of esophageal perforation In severe cases there is circulatory collapse as a result of pain and fluid loss Occasionally significant respiratory obstruction due to edema of the hypopharynx necessitates attention to the maintenance of airway Pain should be relieved with meperidine (Demerol) or opiates With subsidence of the acute phase of poisoning esophageal dilatation and other measures for prevention of strictures should be carried out Delayed perforation may occur

Aminopyrine (Amidopyrine Pyramidon) Over dosage of this drug may produce symptoms resembling those of salicylate intoxication however the drug is mainly of importance because of the frequency with which its use in therapeutic doses is followed by agranulocytosis presumably because of a hypersensitivity reaction (p 1209)

Amphetamine (Benzedrine Dexedrine) Amphetamine and its isomers are widely abused for their exhilarating effects Besides its sympathomimetic action amphetamine is a cerebral stimulant Symptoms of overdosage are tremor dry mouth anorexia nausea diarrhea irritability hallucinations and severe insomnia Hypertension and angina occur particularly in older patients Although there has been a tendency to regard amphetamine as a relatively harmless stimulant which can be used safely in large amounts in comatose patients such as those suffering from barbiturate poisoning evidence indicates that in doses exceeding 300 mg daily there is danger of precipitation of fatal ventricular arrhythmias Administration at any dosage level should cease with appearance of pulse irregularities Treatment consists of barbiturates for sedation and appropriate agents such as quinidine or procaine amide for the purpose of controlling arrhythmias (p 1240)

Aniline This material is chiefly important as an industrial hazard but its use in certain inks dyes crayons and solvents such as paint removers causes occasional poisoning It is absorbed as the vapor or through the skin and poisoning has occurred in infants from exposure to inks used in marking hospital diapers The main manifestation is methemoglobinemia (p 1198)

Antabuse (Disulfuram Tetraethylthiuram Disulfide) See p 755

Antibiotics See p 814

Anticoagulants (Heparin Dicumarol Warfarin) See p 1268

Antihistamines The widespread and unsupervised use of antihistamines makes them readily available for accidental overdosage and suicidal attempts There is wide individual variation in tolerance to these drugs Death due to respiratory depression followed ingestion of only 200 mg of diphenhydramine in one adult while 2 000 mg produced only impaired mentation in another In children the usual toxic manifestations are excitement and convulsions followed by central nervous system depression In adults depressive manifestations predominate with lethargy coma and pupillary dilatation although convulsions followed by further depression can occur Initial treatment should be directed toward removal of unabsorbed drug and the maintenance of adequate respiration and blood pressure Analeptics should be avoided if there is hyperreflexia Should convulsions occur they may be controlled with an ultra short acting barbiturate such as thiopental or with ether to avoid deepening postictal depression Occasionally patients intoxicated with antihistamine drugs which have prominent atropinelike properties may manifest toxic delirium fever mydriasis dry mouth and urinary retention (see Atropine)

Antihypertensive Drugs Toxic effects of drugs used in the treatment of hypertension are described on p 1329

Antimalarial Drugs See p 1113

Atropine (Hyoscyamine Scopolamine Hyoscine Belladonna Stramonium Deadly Nightshade Jimson Weed) When these drugs have been used poisoning is due to therapeutic overdosage in sus

ceptible patients the intranasal use of ophthalmic solutions or to ingestion of plants containing one of these alkaloids There are many so called "solanaceous" plants which contain alkaloids whose action resembles that of atropine or scopolamine

The manifestations of overdosage of atropine are those of parasympathetic blockade central nervous system excitation followed by depression dryness of mucous membranes dysphagia burning of eyes and throat with intense thirst dilated and inactive pupils tachycardia marked flushing and dryness of the skin hoarseness strangury restlessness talkativeness mental confusion and hallucinations progressing to mania Terminally coma and circulatory collapse occur

With scopolamine the pulse is slow there is no flushing of the skin and central nervous system depression with lethargy and somnolence is seen rather than excitement of the type produced by atropine The Babinski response is said to be present in scopolamine poisoning but absent after atropine

Treatment consists of sips of water instillation of mineral oil into eyes and nose to moisten mucous membranes and the use of methacholine or pilocarpine to relieve peripheral symptoms However in the presence of a high degree of block these parasympathomimetic drugs have little or no effect Indeed the absence of effect following the subcutaneous injection of 5 or 10 mg methacholine will confirm suspected poisoning with belladonna alkaloids Gastric lavage should be performed after oral ingestion With atropine cautious sedation may be necessary with scopolamine mild stimulation with caffeine or amphetamine combats depression Catheterization is usually necessary Hyperthermia may occur particularly during hot weather because of inability to sweat If the patient survives for 24 hr death is unlikely but manifestations may persist for several days especially after an overdosage of atropine

Barium Poisoning occurs chiefly from ingestion of rodent poisons containing barium carbonate Rarely soluble barium salts have been given by mistake for x ray purposes in place of the insoluble barium sulfate Barium acts as a stimulant to contraction of all types of muscle producing tremors and spasm in skeletal muscle and hypertension due to arteriolar spasm Its action is particularly pronounced on the intestinal tract where it is manifested by nausea vomiting and abdominal cramps Death usually occurs from increased myocardial irritability with ventricular fibrillation Muscle weakness persists for several days after recovery from acute poisoning Treatment consists of gastric lavage and administration of Epsom salts (to precipitate the barium as insoluble sulfate) supportive measures and the use of quinidine or procaine amide to reduce the danger of fatal cardiac arrhythmia

Benzene Exposure to this solvent occurs chiefly from its use in industry but it may enter the home as a component of dry cleaning solutions paint remover or rubber cement In very large doses it acts as an anesthetic but its chief danger arises from bone marrow depression Susceptibility to this poison appears to vary greatly and exposures which are safe for most people may cause fatal disease in a few Treatment is directed toward the hematologic defect (p 1209) and *complete* protection from further exposure

Beryllium See p 1407

Bleaching Solutions (Sodium Hypochlorite Clorox Purex) The ingestion of sodium hypochlorite solution causes corrosion of the mucosa of the oropharynx and upper gastrointestinal tract Local burning nausea and vomiting are produced Laryngeal edema may occur Lavage with sodium bicarbonate solution is indicated (weak acids should *not* be used) Perforation and stricture formation are rare

Bromides The bromide ion is a central nervous system depressant Although seldom prescribed by physicians at the present time it is still found in many proprietary headache remedies and "nerve tonics" Despite efforts in recent years to curtail the sale of bromides chronic bromide intoxication or bromism is still relatively common Acute poisoning is rare because vomiting commonly follows ingestion of a single large dose However with continued administration bromide accumulates in the body and symptoms of intoxication appear These symptoms are caused by the bromide ion itself and are not a reflection of the decrease in chloride caused by displacement Bromide is handled in the body like chloride being excreted almost entirely via the kidneys although tears sweat and gastric juice also contain the ion Rapid tests for blood bromide are available Although it is generally stated that a blood bromide level of 200 mg per 100 ml (25 mEq/liter) results in the appearance of symptoms higher levels are sometimes well tolerated and severe intoxication is often seen with lower quantities In general the finding of a level of 75 mg per 100 ml (9 mEq/liter) or more must be regarded as confirmatory of the diagnosis of bromism if the clinical picture suggests it

Symptoms range from drowsiness lethargy and dysarthria to coma or mania with psychotic behavior Many patients suffering from bromism were committed to mental institutions in the past Often bromides were prescribed for control of symptoms of unrecognized bromide intoxication A blood bromide determination is indicated in any patient with unusual mental symptoms or unexplained lethargy particularly if a history of drug ingestion is elicited Various types of skin eruptions ranging from acneform lesions to proliferative nodular

lesions not unlike those of tertiary syphilis are also produced by bromides but more than 75 per cent of patients with mental symptoms due to this drug have no dermatitis

Treatment consists of sedation (paraldehyde being the drug of choice) careful nursing and removal of the source of bromide Chloride displaces the bromide ion and promotes its excretion chloride administration may be pursued vigorously but in general with cessation of bromide ingestion and mild chloride supplementation (2 to 4 Gm NaCl three times daily) symptoms subside readily and tremendous doses of sodium or ammonium chloride seem worthwhile only in extreme cases The administration of mercurial diuretics hastens elimination of the drug by promoting a bromide as well as chloride diuresis Hemodialysis with the artificial kidney hastens the excretion of the poison and is probably advisable in severe cases if the necessary equipment is available

Caffeine Although human fatalities due to caffeine are rare overdosage leads to insomnia mild delirium tinnitus tachycardia and prominent diuresis Because caffeine has a direct effect upon the myocardium it may cause serious arrhythmias and dosage should be limited to 6 Gm daily A cup of coffee contains 100 to 150 mg of caffeine The excitatory effects are easily controlled with barbiturates

Camphor Formerly a popular stimulant this drug is now rarely used therapeutically however occasional cases of poisoning are still seen as a result of ingestion of liniment or moth flakes Manifestations are headache sensation of warmth confusion clonic convulsions and terminal respiratory depression The characteristic odor of camphor facilitates the diagnosis Treatment is supportive Barbiturates should be used with caution in combatting convulsions because of postictal respiratory depression Camphor is closely related to thujone formerly the active principle of absinthe which was probably responsible for convulsions in absinthe addicts

Cantharides (Spanish Flies Blistering Beetles Essence of Viper) Poisoning may follow accidental ingestion but is probably commonest after taking cantharides powder for abortion or as an aphrodisiac often as a prank It is a potent irritant and vesicant Symptoms are severe burning pain in the mouth esophagus and abdomen intense thirst bloody diarrhea and hematemesis The vomitus contains shining particles if the powder has been taken There is rapid onset of acute urethritis with painful micturition priapism oliguria hematuria anuria with uremia delirium and death Treatment consists of gastric lavage avoidance of oils or fats (the active principle is fat soluble) morphine for pain and tenesmus and blood and fluid replacement With anuria which is due to glomerular necrosis a regimen for acute renal failure (p 1367) might offer hope for recovery although clinical data on such a trial are lacking

Carbon Monoxide Carbon monoxide is a colorless odorless gas formed by incomplete combustion of carbon containing materials It is a component of manufactured illuminating gas and automobile exhaust fumes and with the exception of alcohol is the most common cause of poisoning treated in hospital emergency clinics The effects of carbon monoxide arise from its ability to form a stable compound with hemoglobin (carboxyhemoglobin) reducing the oxygen carrying capacity of the blood Symptoms include decreased exercise tolerance headache irritability reduced judgment and memory confusion collapse and unconsciousness The symptoms may all appear within a few minutes or may develop gradually if exposure is minimal but prolonged Carboxyhemoglobin is bright red and patients show a characteristic cherry colored flush Cyanosis is absent Treatment is directed toward the breakdown of carboxyhemoglobin by adequate ventilation in the presence of high oxygen tension The patient should therefore be removed from exposure immediately and oxygen inhalation should be instituted Recovery is usually rapid but if tissue anoxia has been prolonged irreversible nervous system damage may have occurred

Carbon Tetrachloride (and Other Halogenated Hydrocarbons) Halogenated hydrocarbons are widely used as industrial solvents Inhaled in sufficient concentration all are capable of inducing narcosis and in addition have varying amounts of hepatic and renal toxicity Household exposure to carbon tetrachloride may occur through use of safe (noninflammable) cleaning solvents or fire extinguishers Absorption may occur following inhalation of fumes in a closed space (3 ml evaporated in a room $10 \times 10 \times 8$ ft yields the maximum safe concentration of 25 ppm) percutaneous absorption or ingestion Renal involvement is said to be more common after inhalation than after ingestion which leads to absorption by the portal venous system The toxic effects of this solvent are greatly enhanced in alcoholics Manifestations are abdominal pain nausea vomiting diarrhea and headache within a few minutes followed in hours or days by progressive damage to liver or kidneys or both The renal lesion can progress to complete anuria with proper fluid management and possibly the use of the artificial kidney survival is possible despite this complication Hepatic damage may be acutely progressive with severe jaundice and rapid death The hepatic lesion is a severe central necrosis Death secondary to pulmonary edema common in the past was due to excessive fluid intake in anuric patients rather than any toxic action on the myo

cardium Spraying carbon tetrachloride on an open flame results in the production of phosgene an even more toxic substance which produces pulmonary edema There is no specific therapy other than gastric lavage and stimulants Management of the renal lesion (p 1367) and a regimen designed to minimize the hepatic damage are indicated

Castor Beans (Ricin) Poisoning by ricin an extremely toxic protein is usually a result of ingestion of castor beans by children Castor bean plants are often raised as ornamental shrubs in this country *Ricinism* is characterized by nausea vomiting and profuse diarrhea with severe dehydration beginning several hours after ingestion of the beans Occasionally convulsions and respiratory depression are a cause of death but the usual picture is one of somnolence progressing to coma Weakness is extreme If the patient survives the acute symptoms there may be anuria and uremia with death after several days There is evidence that this renal lesion is due to a direct action of the poison but the early development of dehydration is undoubtedly an important factor also Ricin has the property of agglutinating erythrocytes in vitro It is uncertain whether this occurs *in vivo* but isolated clinical reports of intravascular clotting make it seem likely that it can play a role in the development of symptoms

Treatment consists of fluid replacement sedation or stimulation as indicated and management of anuria (p 1367)

Chloral Hydrate Poisoning due to this sedative is now rare Differentiation from barbiturate poisoning is usually possible only by history although miosis is said to be commoner with chloral poisoning In addition to its action as a central nervous system depressant chloral exerts a direct toxic effect upon heart liver and kidneys particularly in the presence of preexisting disease Patients who survive death due to respiratory depression during the first few hours may become icteric and die with acute yellow atrophy within a few days Tolerance to chloral rarely develops indeed sudden increases in susceptibility to its effects may result in signs of poisoning in patients taking doses previously well tolerated Chloral is a strong gastric irritant and gastritis is prominent in habituated individuals usually chronic alcoholics There is probably no basis for stories of its potentiation by alcohol in "mickey finns

Colchicine Poisoning is due to accidental ingestion or therapeutic overdosage in the treatment of gout Several hours after oral ingestion, nausea vomiting diarrhea (occasionally bloody) and abdominal pain appear There are progressive weakness and lethargy ascending paralysis with normal mental status and terminal convulsions Death is due to respiratory depression Hematuria and anuria are common but usually transient Treatment is symptomatic

Coramine (Nikethamide) Poisoning due to Coramine is always the result of acute parenteral overdosage and is manifested by intense itching, sneezing and rarely convulsions Duration of action is so short that therapy is seldom indicated although barbiturates may occasionally be helpful

Croton Oil This drastic cathartic has no therapeutic use but poisoning by ignorant pranksters is occasionally seen Croton oil is a strong irritant producing vesiculation and pustulation if applied directly to the skin and a severe hemorrhagic gastroenteritis within 1 to 3 hr after ingestion Death is the result of dehydration blood loss and shock A dose of 20 drops has been fatal for an adult Treatment is supportive with copious parenteral fluids blood replacement and morphine to quiet the bowel

Cyanide Hydrocyanic acid a very volatile material and its sodium or potassium salts are among the most rapidly acting poisons known Hydrocyanic acid is sometimes used for fumigation Cyanide salts are widely used in industry and may reach the home in photographic chemicals or as ingredients of certain types of silver polish Cyanide has a typical bitter almond odor (and has the property in extremely minute concentrations of giving tobacco smoke a peculiar taste chemists working with cyanides often smoke during their exposure to facilitate recognition of minute leaks of the gas into the atmosphere) The fatal dose is small—as little as 300 mg salts or 100 mg hydrocyanic acid gas may cause death Cyanides exert their physiologic effects by combining with iron-containing enzymes such as the cytochromes and catalase with the result that hydrogen and electron transport are blocked (p 463) the energy releasing mechanisms of metabolism cease and death occurs from tissue asphyxia Since the metabolic block is in the tissues rather than the blood the hemoglobin is saturated with oxygen and cyanosis is not seen until respiratory depression supervenes Symptoms depend on the mode of entry of the toxic material When inhaled absorption is so rapid that death may be almost instantaneous hydrogen cyanide has been used for the execution of criminals Oral doses act more slowly requiring several minutes before the appearance of symptoms and as much as an hour for death As the blood cyanide level increases there is headache ataxia nausea profound dyspnea palpitation convulsions and unconsciousness The diagnosis is suggested by the odor of bitter almonds and by the history of abrupt catastrophic onset Treatment must be instituted immediately to be of value The objective is to bind the cyanide in harmless form as the highly stable cyanmethemoglobin This is accomplished by the production of

methemoglobinemia by inhalation of amyl nitrite perles (one every 2 to 5 min unless blood pressure is below 80) followed by intravenous injection of 10 ml of 3 per cent sodium nitrite over a 2 to 4 min period Since speed is essential inhalation is preferable to injection in initiating treatment The use of methylene blue has been advocated but its action is too slow to be of great benefit although it may be given if nitrites are not available The production of methemoglobinemia should be followed by the slow intravenous injection of sodium thiosulfate (50 ml of a 25 per cent solution over a 10 min period) to convert cyanide liberated from the dissociation of cyanmethemoglobin to thiocyanate Norepinephrine or epinephrine may be necessary to maintain blood pressure particularly with the added hypotensive effect of nitrites After nitrites have been given supportive measures may be instituted but unless a considerable degree of methemoglobinemia is produced promptly the outlook is not improved by other forms of treatment

Cyanide is rapidly destroyed in the body by oxidation to relatively harmless thiocyanate If therefore the patient survives a few hours recovery is likely After the acute episode is over there may be residual cerebral symptoms

DDT (*p* Dichlorodiphenyltrichloroethane Chlorophenothane and *Similar Insecticides*) This common ingredient of insecticide powders sprays and aerosols is poorly absorbed unless dissolved in a vehicle such as kerosene or carbon tetrachloride but under these circumstances it readily enters the body through the skin lungs or gastrointestinal tract Fatal poisoning has occurred from the absorption of 150 mg per kg body weight The other related chlorinated diphenyl insecticides and the chlorinated indane insecticides (aldrin Chlordane dieldrin heptachlor) produce toxic manifestations similar to those of DDT Lindane (hexachlorbenzene) produces more striking liver damage The symptoms of acute poisoning are central nervous system hyperexcitability delirium and convulsions followed by progressive depression with paralysis coma and death In chronically exposed patients cerebellar symptoms and evidence of liver damage may develop Treatment consists of gastric lavage barbiturate sedation support of respiration and the alleviation of muscle contractions by intravenous injection of calcium salts Epinephrine should probably be avoided since animal studies indicate an increased susceptibility to epinephrine induced ventricular fibrillation with DDT intoxication Ingestion of fats should be avoided for several days The potential toxicity of the vehicle in which DDT is dissolved should be remembered

Digitalis See p 1312

Ergot (Ergotamine Ergonovine) Poisoning is usually due to illegal use as an abortifacient or to therapeutic overdosage The latter is likely to occur in patients with severe infection liver disease or hyperthyroidism which conditions are contraindications to the use of ergot derivatives Symptoms are nausea and vomiting (relieved by atropine) diarrhea burning abdominal pain (if orally ingested) weakness of legs tingling of extremities severe muscle pains (relieved by massage and calcium gluconate) psychotic behavior and finally convulsions coma and ischemic peripheral gangrene The vascular effects are due to a combination of prolonged vasoconstriction and obstructing intimal hyperplasia and thrombosis Treatment is supportive using nitrites papaverine and mechanical procedures designed to restore circulation and morphine for pain which is often very severe

Favism Ingestion of fava beans or inhalation of its pollen by sensitive individuals results in an acute hemolytic anemia Susceptibility to favism seems to run in families although the disease sometimes appears with no family history of favism often in patients who have eaten the beans for many years Treatment is purely supportive with transfusions etc (p 1187) The disease is rare in this country but has been common in Mediterranean countries particularly Italy

Fluoride *Fluoride salts* are the chief toxic ingredient of many insect poisons When kept in large quantities especially in institutional kitchens they have been mistaken for baking powder or table salt and added to food producing large epidemics of intoxication Fatal poisoning occurs after the oral ingestion of about 2 Gm of the sodium salt Fluoride acts in three ways in the presence of an acid medium e g the gastric contents it forms hydrofluoric acid an exceedingly corrosive material it combines with plasma calcium forming insoluble calcium fluoride causing tetany and it also blocks the glycolytic degradation of glucose thus inhibiting carbohydrate metabolism in the initial steps (p 462) Symptoms are nausea vomiting of corrosive material diarrhea and abdominal pain As the ionized plasma calcium falls muscular hyperirritability progresses from increased reflex activity (positive Chvostek) to fasciculations and convulsive tonic spasms There is circulatory collapse and death usually several hours or rarely several days after ingesting the poison Diagnosis is confirmed by the presence of tetany by the fact that blood drawn from patients poisoned with fluoride clots poorly and by the presence of a high blood glucose concentration The hydrofluoric acid in vomitus may etch glass containers The stomach should be washed at once with lime water calcium chloride or calcium gluconate The skin of the face and perineum should be protected from the corrosive gastrointestinal contents Tetany can

be alleviated and some of the fluoride ion bound harmlessly by the constant slow intravenous injection of very large volumes of 10 per cent calcium gluconate or 1 per cent calcium chloride The infusion rate should be adjusted so as barely to prevent a positive Chvostek sign The hyperglycemia is not reduced by administration of insulin Despite these measures mortality is high in fluoride poisoning The chronic ingestion of fluoride in moderate amounts (20 to 100 mg per day) produces mottling of dental enamel (fluorosis)

Formaldehyde Poisoning due to this substance which is a component of various germicides and fumigants is usually diagnosed by the characteristic odor of formaldehyde in the vomitus Manifestations are largely those of gastrointestinal irritation with nausea vomiting abdominal pain tenesmus difficult micturition and central nervous system depression leading to coma There is striking reduction in plasma carbon dioxide–combining power presumably the acidosis is similar in etiology to that seen after methyl alcohol Treatment is supportive with gastric lavage using dilute ammonia and parenteral infusion of large amounts of sodium bicarbonate or lactate to combat acidosis The fatal dose is about 30 ml

Gases Most fire fighters or victims who are "overcome by smoke are in fact poisoned by carbon monoxide and respond rapidly to oxygen inhalation In some instances however burning material releases irritant fumes either by combustion or by the destruction of containers in which dangerous chemicals have been stored Most of the irritant gases thus released cause *immediate* chemical burns of the upper respiratory tract and exposed skin Ammonia nitrogen oxides (which form nitric acid with water) hydrogen sulfide and sulfur dioxide or trioxide (which form sulfurous and sulfuric acids respectively when hydrated) are chiefly dangerous for their local effects Several hours after exposure has been terminated and when the patient appears comfortable severe pulmonary edema may develop This is usually a result of inhalation of nitrogen dioxide or of phosgene which is released when carbon tetrachloride fire extinguishers are played on hot surfaces One should therefore watch carefully for complications in patients who have been exposed to smoke or burning fumes Treatment includes administration of oxygen control of cough and use of steam inhalations

Gasoline and Kerosene Exposure to the fumes of gasoline in high concentration may lead to headache vertigo unconsciousness with typical muscle jactitations convulsions and death from respiratory depression Treatment consists of administration of oxygen and control of seizures with barbiturates

Oral ingestion of gasoline or kerosene is almost invariably followed by bronchopneumonia the management of which is the main therapeutic problem

Glycols The glycols are dihydric alcohols which are sweet to taste and impart a warming sensation when swallowed Propylene glycol is widely used as a vehicle for drugs and flavoring extracts and is relatively nontoxic Ethylene and diethylene glycol are commonly used in permanent antifreeze compounds and are poisonous Both are metabolized to oxalate in the body Poisoning often results from intentional drinking of antifreeze for supposed alcoholic content Ingestion of ethylene glycol is followed by nausea vomiting deep coma bradycardia clammy skin hypothermia and various neurologic findings such as nystagmus anisocoria absent reflexes and convulsions There is no specific treatment although calcium may be given intravenously in an attempt to reduce the oxalate level Death almost always occurs within 48 hr after massive ingestion from respiratory failure or pulmonary edema

Diethylene glycol produces severe hepatic and renal necrosis with jaundice anuria and uremia Because of the striking renal changes mercury poisoning is often mistakenly suspected in these patients Management of anuria by attention to electrolyte balance etc as for any lower nephron nephrosis (p 1367) appears to be a reasonable therapeutic approach since the renal lesion is reversible

Insecticides and Rodenticides These toxic substances are commonly found in the home and are responsible for a significant number of fatal accidental and suicidal poisonings The clinical manifestations produced depend upon the active ingredients and in some cases upon the toxicity of the solvent Management is discussed under the active ingredients and solvents

Insulin See p 628

Iodine Acute poisoning may follow ingestion of 1 0 ml tincture of iodine or of Lugol s solution and five times this amount may be fatal There is burning abdominal pain nausea and vomiting pallor collapse rapid pulse albuminuria and oliguria Death may occur after an hour or may be delayed for a week Salivation conjunctivitis and edema of the eyelids appear after a few hours Vomitus is blue or black if the stomach contains starch Treatment consists of gastric lavage with starch solution (the blue product is nontoxic) the injection of 10 ml of 10 per cent sodium thiosulfate intravenously every 4 hr to reduce free iodine to less toxic iodide and supportive measures Patients taking iodine for suicidal purposes rarely succeed

Small doses of iodides produce salivation lacrimation coryza fever swelling of the eyelids swelling and tenderness of the salivary glands (iodide

methemoglobinemia by inhalation of amyl nitrite perles (one every 2 to 5 min unless blood pressure is below 80) followed by intravenous injection of 10 ml of 3 per cent sodium nitrite over a 2 to 4 min period Since speed is essential inhalation is preferable to injection in initiating treatment The use of methylene blue has been advocated but its action is too slow to be of great benefit although it may be given if nitrites are not available The production of methemoglobinemia should be followed by the slow intravenous injection of sodium thiosulfate (50 ml of a 25 per cent solution over a 10 min period) to convert cyanide liberated from the dissociation of cyanmethemoglobin to thiocyanate Norepinephrine or epinephrine may be necessary to maintain blood pressure particularly with the added hypotensive effect of nitrites After nitrites have been given supportive measures may be instituted but unless a considerable degree of methemoglobinemia is produced promptly the outlook is not improved by other forms of treatment

Cyanide is rapidly destroyed in the body by oxidation to relatively harmless thiocyanate If therefore the patient survives a few hours recovery is likely After the acute episode is over there may be residual cerebral symptoms

DDT (p Dichlorodiphenyltrichloroethane Chlorophenothane, and Similar Insecticides) This common ingredient of insecticide powders sprays and aerosols is poorly absorbed unless dissolved in a vehicle such as kerosene or carbon tetrachloride but under these circumstances it readily enters the body through the skin lungs or gastrointestinal tract Fatal poisoning has occurred from the absorption of 150 mg per kg body weight The other related chlorinated diphenyl insecticides and the chlorinated indane insecticides (aldrin Chlordane dieldrin heptachlor) produce toxic manifestations similar to those of DDT Lindane (hexachlorbenzene) produces more striking liver damage The symptoms of acute poisoning are central nervous system hyperexcitability delirium and convulsions followed by progressive depression with paralysis coma and death In chronically exposed patients cerebellar symptoms and evidence of liver damage may develop Treatment consists of gastric lavage barbiturate sedation support of respiration and the alleviation of muscle contractions by intravenous injection of calcium salts Epinephrine should probably be avoided since animal studies indicate an increased susceptibility to epinephrine induced ventricular fibrillation with DDT intoxication Ingestion of fats should be avoided for several days The potential toxicity of the vehicle in which DDT is dissolved should be remembered

Digitalis See p 1312

Ergot (Ergotamine Ergonovine) Poisoning is usually due to illegal use as an abortifacient or to therapeutic overdosage The latter is likely to occur in patients with severe infection liver disease or hyperthyroidism which conditions are contraindications to the use of ergot derivatives Symptoms are nausea and vomiting (relieved by atropine) diarrhea burning abdominal pain (if orally ingested) weakness of legs tingling of extremities severe muscle pains (relieved by massage and calcium gluconate) psychotic behavior and finally convulsions coma and ischemic peripheral gangrene The vascular effects are due to a combination of prolonged vasoconstriction and obstructing intimal hyperplasia and thrombosis Treatment is supportive using nitrites papaverine and mechanical procedures designed to restore circulation and morphine for pain which is often very severe

Favism Ingestion of fava beans or inhalation of its pollen by sensitive individuals results in an acute hemolytic anemia Susceptibility to favism seems to run in families although the disease sometimes appears with no family history of favism often in patients who have eaten the beans for many years Treatment is purely supportive with transfusions etc (p 1187) The disease is rare in this country but has been common in Mediterranean countries particularly Italy

Fluoride Fluoride salts are the chief toxic ingredient of many insect poisons When kept in large quantities especially in institutional kitchens they have been mistaken for baking powder or table salt and added to food producing large epidemics of intoxication Fatal poisoning occurs after the oral ingestion of about 2 Gm of the sodium salt Fluoride acts in three ways in the presence of an acid medium e g the gastric contents it forms hydrofluoric acid an exceedingly corrosive material it combines with plasma calcium forming insoluble calcium fluoride causing tetany and it also blocks the glycolytic degradation of glucose thus inhibiting carbohydrate metabolism in the initial steps (p 462) Symptoms are nausea vomiting of corrosive material diarrhea and abdominal pain As the ionized plasma calcium falls muscular hyperirritability progresses from increased reflex activity (positive Chvostek) to fasciculations and convulsive tonic spasms There is circulatory collapse and death usually several hours or rarely several days after ingesting the poison Diagnosis is confirmed by the presence of tetany by the fact that blood drawn from patients poisoned with fluoride clots poorly and by the presence of a high blood glucose concentration The hydrofluoric acid in vomitus may etch glass containers The stomach should be washed at once with lime water calcium chloride or calcium gluconate The skin of the face and perineum should be protected from the corrosive gastrointestinal contents Tetany can

dation of carbohydrate with the consequent accumulation of acid intermediates

Symptoms of poisoning are visual disturbance nausea abdominal pain muscle pain dizziness weakness and various disturbances of consciousness ranging from deep coma to clonic seizures Visual disturbance is almost universal and ranges from mild blurring to total loss of light perception Often impairment of vision is transient although as is well known permanent blindness may follow survival of the acute symptoms Abdominal pain is excruciating and is probably due to pancreatitis which is commonly seen at necropsy Serum amylase is elevated and many cases have been erroneously thought to have surgical disease of the abdomen Likewise cerebrovascular accident is often suspected in sporadic instances of methanol coma Kussmaul respiration may occur but is absent in many severely acidotic patients Abdominal tenderness and spasm are striking and there may be rigidity of the neck Eye findings are helpful the pupils are dilated and nonreactive and ophthalmoscopic examination usually shows typical hyperemia of the optic disk with retinal edema There is no true papilledema and vessel changes are not characteristic

Death in severely acidotic patients is due to cessation of respiration in the phase of inspiration Circulation is often well maintained for several minutes after breathing stops

Treatment consists of intravenous infusion of alkali in large amounts Five per cent sodium bicarbonate is convenient and effective Plasma carbon dioxide–combining power is rapidly restored by this procedure and symptoms of impaired vision abdominal pain etc are dramatically relieved Return of acidosis is frequent and additional alkali may be needed consequently continued observation of patients is advisable Gastric lavage is useless and administration of alkali by mouth is uncertain in nauseated patients Despite considerable experimental evidence indicating that ethanol inhibits the oxidation of methanol to formic acid limited clinical trials of ethanol in preventing acidosis have not seemed beneficial Although administration of whisky or brandy is permissible alkalinization is the mainstay of treatment and should be instituted immediately Overtreatment alkalosis often occurs but is not dangerous and is preferable to undertreatment The eyes should be protected from light until acute symptoms subside

The use of barbiturates to control convulsions and various stimulants such as caffeine or amphetamine is helpful but these procedures are only of transient benefit and correction of acidosis is the primary aim of therapy

Metrazol Poisoning manifested by convulsions is due to therapeutic overdosage and is amenable to barbiturates So violent are convulsions after Metrazol that fractures are a common sequel

Milk Sickness (Snakeroot Richweed Rayless Goldenrod) The ingestion of these plants which contain *trematol* produces the disease in domestic animals known as trembles Human poisoning can result from eating the plant but is most frequent after consumption of the milk or meat of poisoned animals Manifestations are weakness stiffness of the legs anorexia nausea and prostration The tongue and mucosal surfaces are reddened and the breath smells strongly of acetone Circulatory collapse and unconsciousness occur terminally Transient recovery with relapse is common Biochemically there is acidosis acetonuria hypoglycemia and rise in NPN particularly of guanidine The mechanism of action is not clear Death rarely occurs in less than 48 hr and symptoms can persist for several weeks Gastric lavage is useless because symptoms appear after a latent period of several hours Treatment consists of administration of carbohydrate and supportive measures Alcohol was long advocated as an almost specific antidote but there is no basis for its use in therapy

Moth Balls (Paradichlorobenzene Naphthalene) (See also Camphor) These substances are relatively nontoxic except when prolonged massive exposure by inhalation has occurred Under these circumstances they produce central nervous system depression Cataracts have been reported after severe chronic exposure and paradichlorobenzene can produce liver damage if sufficient quantities are absorbed Both materials are relatively safe if swallowed and no specific therapy other than gastric lavage is needed although naphthalene in the form of moth balls or toilet bowl deodorant has been reported a number of times as causing hemolytic anemia after ingestion

Mushroom Poisoning (Mycetismus) There are many poisonous mushrooms but in this country most poisoning is due to *Amanita muscaria* or *Amanita phalloides* After ingestion of *A muscaria* which contains muscarine there is rapid onset of parasympathetic stimulation nausea vomiting diarrhea salivation perspiration lacrimation bradycardia dyspnea with increased bronchial secretion wheezing expiration dilated pupils confusion and excitability Illness begins within 6 hr after eating the mushrooms Recovery usually takes place within 24 hr

Amanita phalloides contains a hepatotoxin and is far deadlier than the muscarine type Six to fifteen hours after eating there is explosive onset of violent abdominal pain vomiting and bloody diarrhea with rapid dehydration and extreme thirst The pupils are normal Within 24 hr in the majority of cases there is onset of jaundice and anuria and death from acute yellow atrophy can occur within

mumps) and skin rash in susceptible individuals Whether these manifestations of *iodism* are due to hypersensitivity or idiosyncrasy to the direct action of the drug itself is not definitely established

Isopropyl Alcohol (Isopropanol Rubbing Alcohol) The diagnosis of isopropyl alcohol intoxication is usually made by its characteristic odor or the finding of an empty bottle of this substance It is approximately twice as toxic as ethyl alcohol and produces profound unconsciousness not unlike that produced by large amounts of its ethyl homologue Coma rarely lasts longer than 8 to 14 hr and treatment with mild stimulants and intravenous fluids is all that is indicated The only threat to life is the irritating action in the stomach which makes vomiting with aspiration a great danger gastric lavage is indicated in all patients Transient acetonuria is common (isopropyl alcohol is oxidized to acetone in the body) but significant acidosis is not seen If intravenous glucose has been given and glycosuria is present the patient may be thought to have diabetes although the confusion is soon corrected by observation of the patient s subsequent course There are no sequelae significant bleeding from gastritis has been reported to complicate convalescence

Local Anesthetics (Procaine Cocaine, Pontocaine Nupercaine Etc) The many drugs in this group vary greatly in toxicity but manifestations of overdosage are so similar that a single description will suffice Poisoning is almost always due to parenteral use of concentrated solution intended for topical use or to overdosage caused by confusion of names Many persons are abnormally susceptible to local anesthetics and manifest symptoms with small doses of procaine the least toxic of the group In sufficient amounts these agents are toxic to the heart and respiratory center and stimulate the central nervous system Mild reactions consist of dizziness dyspnea and pallor In severe poisoning there are convulsions circulatory collapse mydriasis and respiratory failure which may supervene within a period of a few minutes Treatment consists of artificial respiration injection of large doses (0 5 to 1 0 ml) of epinephrine and intravenous injection of a short acting barbiturate Because barbiturates almost specifically counteract the toxic effects of local anesthetic premedication with one of this group of sedatives is advisable before the use of these drugs

Addiction to cocaine in the United States is usually found in individuals who also take morphine The cerebral stimulation produced by cocaine is transient and is soon outweighed by the other effects of the drug The use of cocaine is said to stimulate addicts to crimes of violence It is almost always used by intravenous injection rather than as the old fashioned snuff

Magnesium The magnesium ion is a profound depressant of the central nervous system and of neuromuscular transmission Poisoning is usually due to parenteral administration of magnesium sulfate for hypertension or occasionally to oral or rectal use particularly in patients with renal impairment Manifestations of poisoning are disappearance of reflexes fall in blood pressure hypothermia stupor and respiratory failure Magnesium is toxic for the myocardium but significant cardiac depression is preceded in human beings by respiratory failure The treatment is intravenous administration of a calcium salt which immediately counteracts the untoward effects of magnesium This antagonism between calcium and magnesium on neuromuscular and autonomic ganglionic transmission is due to their reciprocal effect on acetylcholine release

Marihuana (*Cannabis sativa* or Indica Hashish India Hemp Reefers) This narcotic is smoked for *its intoxicating and exhilarating effects* The sequence of events after exposure is not unlike that seen with alcohol but there is more of a tendency to disorientation hallucinations paranoia and particularly a loss of sensation of passage of time The material does not produce tolerance but smokers may become dependent on it for emotional support Overdoses produce severe depression and coma but death is unusual There is no specific treatment The effects are of short duration

Mescaline (Peyote Mescal Buttons) This drug is derived from a species of cactus and is used by Southwestern Indians for ceremonial purposes Its ingestion produces symptoms very similar to those of acute schizophrenia There are colorful pleasurable hallucinations loss of time sense and mild anesthesia Pupils are dilated and there may be bloody diarrhea and unconsciousness after large doses Death is due to respiratory failure There is no treatment other than a supportive regimen

Methyl Alcohol (Wood Alcohol Methanol) Although industrial exposure by inhalation was formerly a hazard methyl alcohol poisoning is now due almost entirely to its ingestion as a substitute for ethanol The toxic dose is extremely variable death has resulted from a dose as small as 20 ml whereas 200 ml has been ingested with survival Methanol is oxidized in the body slowly to formic acid via formaldehyde and the manifestations of poisoning are believed to be due to accumulation of these toxic metabolites This is borne out by the presence in most cases of a lag period of 12 to 24 hr between ingestion and onset of symptoms

The prime manifestation of poisoning is severe acidosis which is not fully explainable on the basis of accumulation of formic acid alone at present the best theory seems to be that formate exerts an inhibitory effect upon enzymes involved in the oxi

An excellent sedative this drug rarely produces respiratory depression even in tremendous dosage (up to 120 ml) although patients may remain unconscious for as long as 48 hr after overdosage Treatment is supportive Morphine and paraldehyde should be used together cautiously because of increased toxicity of this combination Habituation to paraldehyde is occasionally observed among chronic alcoholics who hope to prevent delirium tremens by its use

Phenol and Cresols (Lysol) Poisoning is usually due to ingestion with suicidal intent Diagnosis is facilitated by the characteristic odor of phenol or Lysol Manifestations of poisoning are the same but Lysol requires larger doses for a fatal effect Although poisoning with phenol may cause death within 30 min death may be delayed many hours These substances produce severe erosion of the mucosa of mouth throat esophagus and gastrointestinal tract the burned areas having a characteristic dead white appearance There is vomiting and later diarrhea often with bleeding An initial stage of excitement is followed by coma circulatory collapse and respiratory depression Convulsions are commoner in children than in adults If the patient survives long enough small amounts of urine which darken on standing may be voided Later anuria due to tubular necrosis develops There is often severe acidosis with profound reduction in plasma carbon dioxide—combining power The mechanism of this acidosis is unknown but it may involve some defect in enzyme function such as is seen in methanol or formaldehyde poisoning

Treatment is directed toward removal of the unabsorbed poison by gastric lavage and preventing obstruction of the glottis by edema due to the pharyngeal burns Laryngoscopic inspection should be carried out early and intubation performed if necessary to maintain the airway Rarely tracheotomy may be needed The stomach should be washed with olive oil Because phenol is soluble in ethyl alcohol and alcohol is by far the best substance to use in removing phenol from the skin it is often recommended as a lavage fluid However in contrast to olive oil alcohol will speed the absorption of phenol and is definitely contraindicated for lavage Other treatment consists of infusion of 5 per cent sodium bicarbonate intravenously to combat acidosis (this often produces dramatic improvement) replacement of blood and the use of stimulants and measures to combat shock if blood pressure falls

Chronic exposure to phenol results in pruritus pigmentation of the skin paresthesias and gastrointestinal disturbances Occasionally discoloration of the cartilages similar to that in ochronosis is seen

Phosphorus Elemental phosphorus occurs in several allotropic forms Of these only one yellow phosphorus is appreciably toxic It is an ingredient of certain rat poisons The use of phosphorus in the manufacture of matches has been outlawed as a result of poisoning which occurred in workers in match factories and because of numerous instances of accidental poisoning in children The exact fatal dose is not known

There is burning of the mouth and throat after ingestion and a garlic odor is noticeable on the breath Abdominal pain and vomiting soon become intense When sufficient quantities have been ingested the vomitus glows in the dark Often symptoms subside after a few hours but after 24 to 48 hr *subacute* effects on the liver become apparent and jaundice develops rapidly Death from acute yellow atrophy can occur in a few days

Treatment consists of introducing 100 ml of 1 per cent copper sulfate solution into the stomach and performing gastric lavage The removal of the copper by lavage is imperative After subsidence of acute symptoms a protective regimen for the liver should be instituted and patients should be observed for several days

Picric Acid Poisoning by picric acid can occur from systemic absorption after application to extensive burns from accidental ingestion of solutions or ointments or from exposure in industrial plants Oral ingestion leads to severe gastroenteritis with yellow vomitus There may be hemolysis liver necrosis or acute glomerular damage with hematuria and oliguria in severe cases Picrate is also a central nervous system depressant in large doses Treatment consists of gastric lavage and administration of egg white or cheese (to form insoluble protein picrates) fluid replacement and symptomatic management of gastroenteritis A regimen for acute renal shutdown (p 1367) should be instituted if anuria occurs High concentrations of picrate on the skin produce a severe itching eczema known as picric itch

Picrotoxin Poisoning due to therapeutic overdosage of this drug produces convulsions which are controllable with barbiturates administered intravenously

Pokeroot (Phytolacca) Poisoning is due to ingestion of the root or bark of this plant as a home remedy for arthritis its leaves and berries are innocuous Within 2 hr nausea vomiting and diarrhea occur They are followed by drowsiness vertigo and blurred vision In fatal cases death results from convulsions and respiratory paralysis Treatment is purely supportive and should include gastric lavage if the patient is seen early

Quinidine See p 1242

Salicylates (Aspirin Sodium Salicylate Methyl Salicylate Oil of Wintergreen) The derivatives of salicylic acid are used in larger amounts by the laity and by the medical profession than any other

4 days Recovery is slow after this type of poisoning

Treatment consists of fluid replacement atropine in doses of 0 6 to 1 0 mg in the muscarinic type and barbiturates for persistent excitement Morphine may be required for relief of pain

Mussel Poison During late spring and summer the common Pacific coast mussel sometimes contains a highly toxic material which produces illness and death within a few hours after ingestion of the shellfish It has been determined that the toxin which is not destroyed by cooking is actually a component of certain dinoflagellates which form the diet of the mussel Similar poisoning has been reported in other parts of the world Manifestations which come on within a few minutes are paresthesias of the oral mucosa and extremities progressing to complete anesthesia weakness incoordination ataxia dysarthria and progressive central respiratory depression Circulatory collapse is secondary to hypoxia Survival for 12 hr indicates a good prognosis for life but complete recovery may be prolonged for weeks Treatment consists of gastric lavage the use of artificial or mechanical respiration and supportive measures

Nicotine This alkaloid is an ingredient of many insecticides Poisoning may occur from 150 mg or less equivalent to a few drops of nicotine sulfate (Black Leaf 40) by mouth or inhaled The action of nicotine is a complex mixture of depression and stimulation of the autonomic system and depression of the central nervous system Symptoms consist of gastrointestinal irritation combined with dizziness headache and tachycardia Cortical irritability culminating in convulsions and myocardial irritability with arrhythmias precede death which is usually the result of cardiac or respiratory arrest Although atrophine will counteract many of the peripheral autonomic disturbances (salivation miosis blurred vision) caused by nicotine it is ineffective in preventing respiratory or cardiac failure Supportive treatment directed toward maintenance of oxygenation and prevention of arrhythmias (p 1240) is therefore of great importance

Nitrites These compounds are of importance chiefly because of their ability to produce methemoglobin (p 1198) While these materials are usually administered therapeutically (the nitrites as amyl nitrite or nitroglycerine) accidental poisoning occasionally occurs from contamination of poorly capped wells with nitrate producing soil bacteria

Nitrogen Mustards See p 1226

Organic Phosphate Insecticides Numerous newly developed insecticides including Parathion (*diethyl p nitrophenyl thiophosphate*) TEPP (*tetra ethyl pyrophosphate*) HRTP (hexaethyl tetraphosphate) OMPA (octamethyl phosphoramide) EPN (ethylphenyl p nitrophenyl thiophosphate) Systox (diethyl 2 ethyl mercaptoethyl thiophosphate and Mipafox (bis monoisopropylamino fluorophosphine oxide) are potent inhibitors of cholinesterase and have been responsible for fatal poisoning in man No deaths yet have been attributed to Malathion a similar anticholinesterase insecticide These materials are usually prepared for use by dilution with inert powder organic solvents or water They are rapidly absorbed by inhalation through intact skin or by ingestion Since cholinesterase destroys the acetylcholine liberated by the central nervous system autonomic ganglions parasympathetic nerve endings and motor nerve endings symptoms are produced by the persistent action of acetylcholine at these sites Clinical manifestations of poisoning are blurring of vision and miosis rhinorrhea salivation sweating nausea vomiting abdominal cramps diarrhea dyspnea tightness of the chest bronchospasm bronchorrhea cyanosis muscular cramps and fasciculations followed by flaccid paralysis convulsions coma and respiratory depression Management consists of removal of contaminated clothing and gentle cleansing of the skin with soapy water Application of a tourniquet will delay systemic absorption from a contaminated extremity Atropine will block parasympathetic and central neural effects It should be given promptly and in large doses (1 to 2 mg intravenously) This dose may be repeated at 3 to 8 min intervals until parasympathetic manifestations are controlled (miosis often persists even with adequate atropinization) After control of symptoms the interval between doses is judged by return of mild symptoms Total doses as large as 20 mg per day are often necessary for severe poisoning Since atropine has no effect on the muscular paralysis artificial respiration may be necessary Careful attention should be paid to the removal of bronchial secretions Barbiturates may be required if convulsions persist despite full atropinization Patients who survive for 24 hr usually recover without residua although symptoms may persist for several days

Oxalates Poisoning from oxalates occurs chiefly from ingestion of ink eradicators or stain removers containing oxalic acid They produce burning of the mouth nausea vomiting and abdominal pain Later formation of insoluble calcium oxalate produces hypocalcemic tetany Anuria from blockage of ureters by calcium oxalate has been reported Treatment of acute poisoning consists of the oral and intravenous administration of calcium salts (e g calcium gluconate or chloride) and a supportive regimen

The leaves of rhubarb contain large amounts of *oxalic acid* and acute poisoning has followed their ingestion

Paraldehyde The diagnosis of paraldehyde poisoning is made easy by its characteristic odor

indicated as for any comatose patient Morphine which is a medullary depressant but a spinal cord stimulant is contraindicated

Sulfonamides See p 814

Turpentine Turpentine is readily absorbed from the skin intestine or lungs and is excreted in the urine which is said to have an odor of violets Chronic exposure to turpentine leads to urethritis a common symptom among painters Ingestion of large amounts (usually for its supposed abortifacient effect) produces colic nausea vomiting diarrhea delirium ataxia and coma If the acute stage of poisoning is survived there may be painful micturition albuminuria hematuria and on occasion anuria and acute renal shutdown due to tubular necrosis Treatment is supportive a regimen for anuria should be instituted (p 1367) since the renal lesion is reversible

Vitamins A and D See pp 525 and 527

medication Therapeutic poisoning usually results from the cumulative effect of prolonged high dosage for rheumatic fever arthritis of other types etc but accidental poisoning or suicidal attempts account for an appreciable number of cases There is considerable variation in susceptibility to the toxic effects of salicylates idiosyncrasy is common but instances of great resistance are also seen Toxic symptoms may begin at dosages of 3 to 4 Gm per day or may not appear when as much as 10 Gm per day is given The plasma salicylate level is almost always greater than 10 mg per 100 ml when symptoms appear and the development of hyperventilation usually reflects a level of over 40 mg per 100 ml The earliest manifestations are vertigo tinnitus and deafness These signs may subside if treatment is interrupted briefly or even if administration is continued If overdosage continues nausea vomiting headache and various types of mental aberration develop Occasionally there may be great excitement restlessness and talkativeness —the so called salicylate jag At this point the patient usually shows the typical salicyl dyspnea Both vomiting and hyperventilation are due to an effect of the salicylate directly on the central nervous system Early in the development of the syndrome serum electrolytes and the carbon dioxide-combining power are usually normal but as increased urinary loss of alkali compensates for the respiratory alkalosis there is progressive diminution in both serum sodium and carbon dioxide-combining power As this stage is reached there is usually a mild ketosis the result of dehydration and starvation After ingestion of a single large dose of salicylates the development of symptoms may be extremely rapid so that the stage of dehydration ketosis and hyponatremia is reached within a few hours Laboratory examination shows albuminuria hematuria and a false positive ferric chloride test for urinary ketone bodies Experimentally salicylates have been shown to produce hypoprothrombinemia and occasional instances of increased bleeding due to salicylates have been reported in man However salicylate hypoprothrombinemia is uncommon and is not a regular manifestation of poisoning by these drugs Treatment consists of stopping salicylates and of fluid replacement Vitamin K is indicated if there is evidence of excess bleeding Since the reduction in serum sodium is actually a manifestation of alkalosis hypertonic saline solution is helpful However sodium bicarbonate is advocated particularly because it reduces the renal threshold for salicylates enhances excretion and thereby shortens the clinical course Hemodialysis with an artificial kidney has been used with success Although the mortality from therapeutic salicylate poisoning is small it has been as high as 50 per cent in a small series of accidental or suicidal intoxications Methyl salicylate poisoning is particularly dangerous in children who are often attracted by the smell of wintergreen

"Smog" This slang term is used to describe dense fog in which smoke and chemical fumes are also present It is usually merely irritating but under special circumstances industrial waste gases such as hydrogen sulfide sulfur dioxide or the nitrogen oxides may introduce a definite risk of poisoning Although morbidity is sometimes high only among elderly patients with chronic cardiac or pulmonary disease is there danger of death Treatment is removal from the smoky environment If this is impractical the use of an oxygen tent or mask may prevent serious difficulties in susceptible patients

"Smoke" A large number of paint removers lacquer thinners antifreezes and other solvent mixtures are ingested at one time or another for their supposed alcohol content Because of their milky appearance when diluted with water these mixtures are referred to as smoke in many localities although other names are used Some wholly unknown component of these materials occasionally causes a profound hypoglycemia with coma clammy skin and bizarre neurologic signs This disturbance should be considered in any alcoholic who remains stuporous after the usual treatments for alcoholic coma have been tried The injection of 50 per cent glucose intravenously produces dramatic results in these patients and should not be delayed until the suspected diagnosis can be confirmed by laboratory test Patients should be observed carefully for a few hours after treatment because hypoglycemia may recur

Strychnine Poisoning often results from ingestion of A S and B cathartic pills by children eating poisoned grain or suicidal attempts The effect of strychnine is to increase the irritability of the entire nervous system and prolong the period of hyperexcitability after a normal stimulus The patient remains conscious and acutely aware of his surroundings After a period of heightened irritability and muscle twitching tonic seizures occur in which there is opisthotonos rigid extension of the legs facial tetanus producing the *risus sardonicus* and apnea due to spasm both of the diaphragm and of muscles of the abdomen and thorax Each convulsion lasts 1 to 2 min Death from anoxia may follow two to five seizures

Barbiturates should be given rapidly to control convulsions and hence prevent anoxia and death Secondary measures such as lavage etc must await sedation for any stimulus may set off a seizure Observation for 24 to 48 hr is necessary any sign of increased irritability calls for more sedation During this period supportive care is

104 DISORDERS DUE TO HIGH ENVIRONMENTAL TEMPERATURE

T R Harrison

The clinical syndromes resulting from excessive environmental temperature are of three types designated respectively as heat cramps heat exhaustion and heat pyrexia (heat stroke) These disorders are especially common during the first few days of a heat wave before acclimatization has occurred After the adaptive process to stress has caused decline in the amount of sodium in the sweat the disorders are less common and the need for administration of sodium chloride as a preventive measure is less urgent

Heat Cramps This disorder occurs in individuals who develop diminished osmolar concentration of body fluids because they sweat excessively and drink water copiously It has been especially common in the past in stokers and miners The chief symptom is pain due to spasms of skeletal muscles The blood and urine display diminished concentration of sodium and chloride The disorder may be prevented by the use of dilute sodium chloride solution instead of water for drinking purposes or by the ingestion of sodium chloride Treatment consists in the administration of isotonic or slightly hypertonic sodium chloride solution or of enteric coated tablets until the symptoms of the disorder are relieved

Heat Exhaustion This is a common and usually mild disorder which occurs during excessively hot weather It seems to be more common in women than in men and is more likely to occur in persons not acclimatized to hot weather The syndrome appears to be related either to vasomotor changes with distributional shift of blood from visceral areas to the skin or to slight decline in total extracellular fluid volume The chief symptoms are lassitude and faintness but actual syncope may occur Sweating may be profuse and the body temperature undergoes little or no change Prevention consists of reduction of physical activity during excessively hot weather (and especially when the individual is unaccustomed to such weather) the use of electric fans and the free ingestion of water and sodium chloride The enteric coated tablets of sodium chloride are less likely to cause nausea but may be excreted by patients with diarrhea

Heat Pyrexia (Heat Stroke Sunstroke) This condition while less common is of great importance because of its gravity and because of its curability provided treatment is instituted soon enough and is energetically pursued The disorder is particularly common in aged infirm or alcoholic persons It likewise occurs frequently in those who without gradual acclimatization, travel rapidly into excessively hot localities It is especially common during the first few days of a "heat wave" Physical exertion is apparently a predisposing factor The striking predominance of the disorder in males is probably referable to the difference in the habits of the two sexes as regards exertion and alcoholic sprees The occurrence of the disorder is intimately related to humidity as well as temperature Thus heat pyrexia may be encountered with environmental temperature as low as 32 C (90 F) when the humidity is high but is very rare below temperatures of 38 C (100 F) in areas of low humidity

The classic *manifestations* of heat pyrexia are a *rapidly mounting body temperature in the presence of a dry hot skin occurring in an individual exposed to an excessively high environmental temperature* The temperature may reach excessive heights values of 44 C (112 F) being seen occasionally The

104 DISORDERS DUE TO HIGH ENVIRONMENTAL TEMPERATURE

T R Harrison

The clinical syndromes resulting from excessive environmental temperature are of three types designated respectively as heat cramps heat exhaustion and heat pyrexia (heat stroke) These disorders are especially common during the first few days of a heat wave before acclimatization has occurred After the adaptive process to stress has caused decline in the amount of sodium in the sweat the disorders are less common and the need for administration of sodium chloride as a preventive measure is less urgent

Heat Cramps This disorder occurs in individuals who develop diminished osmolar concentration of body fluids because they sweat excessively and drink water copiously It has been especially common in the past in stokers and miners The chief symptom is pain due to spasms of skeletal muscles The blood and urine display diminished concentration of sodium and chloride The disorder may be prevented by the use of dilute sodium chloride solution instead of water for drinking purposes or by the ingestion of sodium chloride Treatment consists in the administration of isotonic or slightly hypertonic sodium chloride solution or of enteric coated tablets until the symptoms of the disorder are relieved

Heat Exhaustion This is a common and usually mild disorder which occurs during excessively hot weather It seems to be more common in women than in men and is more likely to occur in persons not acclimatized to hot weather The syndrome appears to be related either to vasomotor changes with distributional shift of blood from visceral areas to the skin or to slight decline in total extracellular fluid volume The chief symptoms are lassitude and faintness but actual syncope may occur Sweating may be profuse and the body temperature undergoes little or no change Prevention consists of reduction of physical activity during excessively hot weather (and especially when the individual is unaccustomed to such weather) the use of electric fans and the free ingestion of water and sodium chloride The enteric coated tablets of sodium chloride are less likely to cause nausea but may be excreted by patients with diarrhea

Heat Pyrexia (Heat Stroke Sunstroke) This condition while less common is of great importance because of its gravity and because of its curability provided treatment is instituted soon enough and is energetically pursued The disorder is particularly common in aged infirm or alcoholic persons It likewise occurs frequently in those who without gradual acclimatization, travel rapidly into excessively hot localities It is especially common during the first few days of a heat wave Physical exertion is apparently a predisposing factor The striking predominance of the disorder in males is probably referable to the difference in the habits of the two sexes as regards exertion and alcoholic sprees The occurrence of the disorder is intimately related to humidity as well as temperature Thus heat pyrexia may be encountered with environmental temperature as low as 32 C (90 F) when the humidity is high but is very rare below temperatures of 38 C (100 F) in areas of low humidity

The classic *manifestations* of heat pyrexia are a *rapidly mounting body temperature in the presence of a dry hot skin occurring in an individual exposed to an excessively high environmental temperature* The temperature may reach excessive heights values of 44 C (112 F) being seen occasionally The

patient at first apathetic becomes stuporous and then deeply comatose as the temperature rises The skin remains hot and dry throughout but striking and abrupt changes in color may occur The flushed appearance which is usually striking in the early stages may suddenly be replaced by a grayish pallor Such a change indicates the onset of circulatory collapse and the imminence (or presence) of irreversible damage to vital structures This alteration in the color of the skin is associated with other striking alterations in the clinical pattern The circulatory state is initially that of increased cardiac output (full bounding pulse high pulse pressure prominent visible arterial pulsations exaggerated heart sounds) This state changes to that characteristic of peripheral circulatory failure (Chap 17) Congestive heart failure may occur in patients suffering from preexisting cardiac disease or in persons treated with excessive amounts of fluid by the intravenous route

Hyperpyrexia produces extensive parenchymal damage in the various organs Petechial hemorrhages occur diffusely and especially in the brain and in the skin Patients surviving the disorder may display for prolonged periods clear indications of cerebral cardiac renal or hepatic injury Of particular interest is the neurologic disorder If the patient survives the heat stroke he may be left with a remarkable degree of cerebellar ataxia This first becomes manifest as he emerges from coma and for a time there is a mixture of confusion slurred speech and inability to stand and walk With further recovery the patient's mind usually becomes clear and the cerebellar ataxia is then observed in almost pure form It may be permanent

The *pathogenesis* of the disorder remains obscure The visceral damage is clearly the result of the hyperthermia *The Purkinje cells of the cerebellum* are particularly vulnerable to high temperature The immediate cause of death is peripheral circulatory failure in most instances but may be heart failure in the case of patients given too much intravenous fluid at too rapid rates The sudden onset of peripheral circulatory failure is apparently due to the replacement of the initial circulatory adjustment—visceral constriction with cutaneous dilatation—by visceral dilatation with secondary cutaneous constriction The decline in cutaneous blood flow now participates in the vicious cycle The elevation of metabolism due to the hyperthermia causes further rise in temperature The initial inability to lose heat by evaporation of sweat is now complicated by inability to lose heat by radiation to the surrounding air because insufficient blood is flowing through the skin

The rise in body temperature is clearly due to the cessation of sweating The unsolved question involves the mechanism of the sudden cessation of sweating Certain individuals with congenital or acquired disorders of sweat glands have marked impairment of the capacity to sweat and must avoid hot weather Fatigue of the sweat glands appears to be the responsible mechanism in most instances

The *diagnosis* of heat pyrexia is usually made readily With the exception of intracranial disorders the condition is the only common cause of a temperature higher than 42 C (108 F) in an adult It is the only common condition in which *the combination of a rising temperature and a hot dry skin* is seen The only conditions likely to cause confusion are other causes of high body temperature but in almost all these the skin is either dry cold and pale (in the stage of rising temperature) or moist warm and flushed (in the stage of sustained or declining fever) It is a wise rule to consider all adult patients observed during very hot weather with a temperature of 41 C (106 F) or more to be suffering from this disorder unless another cause can be demonstrated immediately It is far better to treat an occasional patient who does not have heat pyrexia than to fail to institute immediate therapy when this condition is present

The proper management of heat pyrexia depends upon the realization that *the damage done to vital structures by a given level of hyperthermia depends on the time factor* A certain temperature for a certain time may produce irreversible alterations while the same temperature for a shorter time may lead only to reversible ones During periods of excessively hot weather all hospitals should keep a tub filled with water and ice The moment a patient with a temperature of 40.5 C (105 F) or more who also has warm and dry skin enters the hospital he should be immersed in this tub and *given massage to promote vasodilatation and heat* loss After the rectal temperature reaches 38 C (100 F) the patient should be removed to a bed and the temperature measured every few minutes wet sheets and a fan being employed if it tends to rise again or warm blankets if it declines below the normal level It has been shown in controlled experiments on animals that immersion in ice water is definitely superior to the evaporative management in terms of the all important objective of producing rapid decline in body temperature and there is strong evidence that the same conclusion is valid *in human beings*

When peripheral circulatory failure exists after the temperature has been reduced to a normal level intravenous fluids are indicated but with due consideration of the facts that many of the elderly patients with the disorder have diminished myocardial reserve and that heat pyrexia has been shown to impair the functional integrity of the heart When heart failure supervenes as is occa

sionally the case digitalis and the other procedures valuable in treating rapidly developing heart failure (Chap 226) are indicated

The prognosis is very grave in patients with heat stroke but the immediate and rapid reduction of body temperature often saves lives which would otherwise be lost

105 HYPOTHERMIA AND COLD INJURY

Albert R Behnke and Ralph W Brauer

The employment of low temperature to induce hypothermia in surgical patients for the purpose of reducing blood flow and oxygen requirements of organs has been a noteworthy development in recent years It has been possible by this means to perform operations on the heart brain and even the liver which heretofore have not been feasible Advancements in physiologic techniques are making possible requisite basic studies of oxygen requirements and blood flow to the brain liver (Brauer technique) and other organs when cryo-procedures are employed

It has been possible to reanimate without residual injury small animals with body temperatures cooled to the freezing level (Andjus Smith Lovelock) In the cooled animal cardiorespiratory function and the electrical activity of the brain are brought to cessation and as much as 33 per cent of the total body water may be solidified into ice crystals Of immediate practical application is the fact that frozen hamsters did not develop frostbite in the extremities unless manipulation or mild trauma was inflicted when the animal was in a state of cryorigidity (Smith)

Meryman has outlined the two avenues of approach in freezing biologic materials without injury viz (1) slow freezing with extracellular crystal formation and a resultant high concentration of electrolytes attending the extraction dehydration and (2) rapid freezing forming intracellular crystals sufficiently small so as to be benign In slowly frozen blood it appears to be dehydration and electrolyte concentration and not ice crystal formation which produce hemolysis (Lovelock)

With respect to cold injuries progress may be exemplified by the Korean (U S Army) studies and the investigations in Alaska by Irving and Scholander The following treatises may be cited "Physiology of Heat Regulation and the Science of Clothing" edited by Newburg and "Temperature and Human Life" by Winslow and Herrington A systematic elucidation of the acute effects of cold particularly the role of cold as a prime nonspecific stressor agent is to be found in Selye s book "Stress" The Arctic Institute has prepared six volumes to date which serve as source material the Macy Foundation Conferences on Cold Injury (proceedings edited by Ferrer) also provide source material Finally analysis of physiologic problems especially valuable for physicians will be found in the monograph by Burton and Edholm A detailed clinical study and analysis of the immersion foot syndrome has been made by Ungley

Physiologic Considerations and Tolerance Limits *Vasoconstriction and Dilatation* The effects both physiologic and pathologic of cold are inextricably bound up with the two major responses of blood vessels viz vasoconstriction and vasodilatation Unchecked or exaggerated they are associated either with tissue anoxia or with fulminating vascular reactions destructive of tissue

The immersion of fingers in ice water will demonstrate the relationship between vasoconstriction and pain and the periodic relief afforded by the local oscillatory vasodilatation and constriction the hunting phenomenon of Sir Thomas Lewis Blood flow in the extremities after reaching minimal values between 15 and 18 C (59 to 64 4 F) is greatly augmented apparently through arteriovenous shunts at temperatures between 0 and 8 C (32 to 46 4 F) In this temperature range arterialized blood can be withdrawn from the veins of the hand previously immersed in ice water Blood flow in the chilled

appendage can be greatly modified by warming or cooling the body as a whole (Spealman)

Blood and Metabolic Changes Lung ventilation rate arterial pressure and pulse rate parallel oxygen consumption with a rise during the euphysiologic state and a fall when compensation is broken as in immersion hypothermia

Blood volume changes increased viscosity of blood hemoconcentration diuresis (apparently under posterior pituitary control) and increased hormonal activity are factors influencing the course of cold injury Cold stimulation of the thyroid and adrenal glands may represent the acute response of unacclimatized animals or individuals very similar to the stimulation induced in unacclimatized individuals subjected to altitude hypoxia

Limits of Tolerance to Cold The opportunity to study participants during swimming trials (1955) in the English Channel by Pugh and Edholm and others focuses attention upon the remarkable ability of the trained athlete to maintain a normal deep body temperature for periods of 15 hr or more under conditions in which water and skin temperatures (about 15 C 59 F) are some 38 F lower than deep body temperature Such factual data lend support to the useful concept of a body core insulated by a body shell With vasoconstriction operative in cold water a virtual cut off of peripheral circulation serves to maintain deep body temperature by minimizing loss of heat and to effect what amounts to an autotransfusion There is great individual variability in heat loss when the body is immersed in cold water A relatively obese swimmer for example maintained a normal rectal temperature for 2 hr without shivering when he was immersed up to his neck in water with a temperature of 16 C A lean man under the same conditions despite violent shivering experienced a fall in rectal temperature of several degrees and had to be assisted from the water tank because of partial incapacitation from rigor In water colder than 10 C (50 F) man cannot produce sufficient heat to maintain thermal balance for long periods and cooling proceeds rapidly toward temperature levels that cause serious functional impairment

A skin temperature of the fingers of about 10 C (50 F) is the lower limit for the maintenance of a reasonable degree of manual dexterity in unacclimatized persons On the other hand Eskimos have been known to perform some remarkable manipulative feats with their bare hands at specific tasks in subzero weather

In hypersensitive persons exposure to ordinary degrees of cold may produce immediate or general reactions such as asthma hives vascular spasm vomiting neuralgia convulsions and syncope the latter apparently by a histaminelike effect on capillaries with pooling of blood in the periphery Many of these patients can be desensitized by gradual exposure to cold or by subcutaneous injections of histamine The subject of cold agglutinins is a matter for reference

ACCLIMATIZATION The nice distinction has been made by Hart (cited by Burton and Edholm) between *acclimatization*—changes in the responses of an organism produced by continued alterations in the environment *acclimation*—alterations related to changes in a lifetime and *adaptation*—changes occurring during a period of several generations

Although some primitive peoples live at zero or even subzero temperatures wearing little or no clothing it has not been possible to provide conclusive data on human beings at these temperatures (though it has for lower animals) which clearly distinguish between the acclimatized and even the adapted individual compared with the unacclimatized person (Such data are available for human beings with regard to heat acclimatization) Polar explorers have reported appreciably decreased clothing requirements relative to time of stay in the cold atmosphere Moreover the winter comfort zone as defined by the American Association of Heating and Ventilating Engineers shows a decrease of some 5 F in winter temperatures compared with the summer level Healthy individuals following infancy are remarkably tolerant to acute exposures in cold air or water in the benign range of temperature and living in relatively cold rooms (60 to 65 F) has been consistent with good health and not attended by the respiratory difficulties associated with an indoor air environment of 80 to 85 F during the winter season

Immersion Hypothermia It is convenient to divide responses in cold water immersion into three stages (1) stimulatory—deep body temperature (DBT) normal to 35 C (95 F) (2) depressant—DBT 35 to 30 C (3) critical—DBT 30 to 25 C (86 to 77 F) Apparently 30 to 25 C may be a critical zone since it is possible to cool small animals to 0 C (Andjus and Smith)

Cardiovascular Responses With respect to cardiovascular responses of individuals immersed up to the neck in cold water (5 to 15 C) the initial vasoconstriction is followed by a slight rise of rectal temperature and a transient rise in blood pressure and heart rate The heart rate then decreases in response to the action of low temperature on the pacemaker In contrast with the bradycardia associated with the inhalation of oxygen at normal or at high pressures bradycardia due to low temperature is not abolished by atropine or vagotomy Bradycardia is a striking response to hypothermia

At rectal temperatures of 30 C (86 F) arrhythmias may appear and auricular fibrillation is common When the deep body temperature reaches a level of about 25 C (77 F) there occurs in the dog

a precipitous fall in blood pressure and death supervenes at about 22 C from ventricular fibrillation Of interest are experiments on dogs in which Lian and subsequently Riberi and Shumacker blocked the sinoauricular area with procaine and thereby lessened myocardial irritability and the occurrence of ventricular fibrillation It is the depression of metabolism that renders hypothermia of value in surgery Blood flow and oxygen consumption may be reduced to about 25 per cent of the normal resting level (heart rate 15 to 20 beats per minute) in the DBT range of 25 to 30 C (77 to 86 F) In dogs Rosonoff and Duncan found that cerebral blood flow decreased in proportion to the temperature fall from 35 to 25 C (DBT) there was a two thirds reduction of blood flow to the brain

Employment in Surgery Hypothermia is a crucial procedure but it is possible to deprive vital organs—e g the heart—of blood for periods up to 10 min followed by recovery of normal function (Lewis) The time of exposure to the low temperature must be limited and a great deal more knowledge than now available is required before the procedure is generally acceptable

Hypothermia can be induced with light anesthesia and surface cooling by means of air water or blankets through which brine is circulated at freezing temperatures French physiologists (Laborit Huguenard) on the assumption that the above outlined procedure is traumatic attempted to provide pharmacologic means to induce hypothermia more smoothly through the administration of multicomponent solutions containing either chlorpromazine or certain hydrogenated ergot alkaloids A review of 1 100 cases in which chlorpromazine was used as an adjunct to premedication is given by Lear Chiron and Pallin

Rewarming With respect to rewarming following hypothermia Burton and Edholm conclude that the proper procedure is to restore normal body temperature either slowly or by rapid rewarming (water bath 45 C) There is no middle course In acute immersion experiments there is no question about the beneficial effects of rapid rewarming in water 45 C (113 F) during the initial recovery period to circumvent the further drop in DBT caused by cold peripheral blood lowering the temperature of the body core When the peripheral tissues are warm however the individual should be removed from the bath even though DBT is below normal in order to forestall circulatory collapse from vasodilatation and excessive diversion of cardiac output to the periphery Following long periods of immersion the over all applicability of rapid rewarming is not conclusive because of the probability of depletion of liver and cardiac muscle glycogen and of large fluid shifts resulting in a greatly decreased blood volume In therapeutic hypothermia (Talbott) when low rectal temperatures of 25 to 27 C were maintained for as long as 48 hr rewarming was carried out at room temperature

Local Cold Injury If the injurious responses to cold are divided into freezing (frostbite) and nonfreezing (immersion foot) types of injury then Meryman's diagram (Fig 135) outline differences and similarities in both types of injury The two types of injury may be observed in the same extremity or in different extremities in the same individual e g trench foot or freezing in the hands and nonfreezing in the feet of shipwreck survivors Moreover it is important to recognize as pointed out by Ungley the differences in clinical appearance signs and symptoms underlying pathologic derangements and sequelae of the two entities which may require divergent courses of therapy The diagnosis of freezing versus nonfreezing injury can be made generally on the basis of history and clinical signs and symptoms in the two conditions For classical descriptions of the nonfreezing type of injury or immersion foot syndrome reference is made to the excellent papers of White and of Ungley

Immersion Foot In this entity observed in shipwreck survivors or in soldiers (trench foot) whose feet have been wet but not freezing cold for prolonged periods there is primarily injury to nerve and muscle tissue with essentially no gross or irreparable pathologic changes in blood vessels and skin The clinical picture is in harmony with the results to be anticipated from primary hypoxic trauma and lends itself to a description of three clearly recognizable states (1) ischemia denoted by a pale pulseless extremity (2) hyperemia denoted by a bounding pulsatile circulation for example in red swollen painful feet and (3) a post hyperemic recovery period The initial cold induced vasoconstriction increased blood viscosity and impaired oxygen transport in the ischemic state are augmented by such factors as undernutrition general hypothermia dehydration and trauma from relatively fixed pendent extremities The problem of rewarming pertains to these patients during the stage of ischemia when overheating of tissue may lead to gangrene In the stage of hyperemia the red swollen feet require judicious cooling as indicated by White and by Ungley

It may be helpful to consider this type of injury as a peripheral neuropathy following chilling (Ungley) i e as giving rise to manifestations of the Raynaud syndrome essentially free (to be sure in the state of hyperemia) from the vascular restriction and occlusion seen in Buerger's disease In its mildest form it can be induced in the feet for example in whole body immersion experiments of only 1 hr duration when the bath temperature

appendage can be greatly modified by warming or cooling the body as a whole (Spealman)

Blood and Metabolic Changes Lung ventilation rate arterial pressure and pulse rate parallel oxygen consumption with a rise during the euphysiologic state and a fall when compensation is broken as in immersion hypothermia

Blood volume changes increased viscosity of blood hemoconcentration diuresis (apparently under posterior pituitary control) and increased hormonal activity are factors influencing the course of cold injury Cold stimulation of the thyroid and adrenal glands may represent the acute response of unacclimatized animals or individuals very similar to the stimulation induced in unacclimatized individuals subjected to altitude hypoxia

Limits of Tolerance to Cold The opportunity to study participants during swimming trials (1955) in the English Channel by Pugh and Edholm and others focuses attention upon the remarkable ability of the trained athlete to maintain a normal deep body temperature for periods of 15 hr or more under conditions in which water and skin temperatures (about 15 C 59 F) are some 38 F lower than deep body temperature Such factual data lend support to the useful concept of a "body core" insulated by a "body shell" With vasoconstriction operative in cold water a virtual cut off of peripheral circulation serves to maintain deep body temperature by minimizing loss of heat and to effect what amounts to an autotransfusion There is great individual variability in heat loss when the body is immersed in cold water A relatively obese swimmer for example maintained a normal rectal temperature for 2 hr without shivering when he was immersed up to his neck in water with a temperature of 16 C A lean man under the same conditions despite violent shivering experienced a fall in rectal temperature of several degrees and had to be assisted from the water tank because of partial incapacitation from rigor In water colder than 10 C (50 F) man cannot produce sufficient heat to maintain thermal balance for long periods and cooling proceeds rapidly toward temperature levels that cause serious functional impairment

A skin temperature of the fingers of about 10 C (50 F) is the lower limit for the maintenance of a reasonable degree of manual dexterity in unacclimatized persons On the other hand Eskimos have been known to perform some remarkable manipulative feats with their bare hands at specific tasks in subzero weather

In hypersensitive persons exposure to ordinary degrees of cold may produce immediate or general reactions such as asthma hives vascular spasm vomiting neuralgia convulsions and syncope the latter apparently by a histaminelike effect on capillaries with pooling of blood in the periphery Many of these patients can be desensitized by gradual exposure to cold or by subcutaneous injections of histamine The subject of cold agglutinins is a matter for reference

ACCLIMATIZATION The nice distinction has been made by Hart (cited by Burton and Edholm) between *acclimatization*—changes in the responses of an organism produced by continued alterations in the environment *acclimation*—alterations related to changes in a lifetime and *adaptation*—changes occurring during a period of several generations

Although some primitive peoples live at zero or even subzero temperatures wearing little or no clothing it has not been possible to provide conclusive data on human beings at these temperatures (though it has for lower animals) which clearly distinguish between the acclimatized and even the adapted individual compared with the unacclimatized person (Such data are available for human beings with regard to heat acclimatization) Polar explorers have reported appreciably decreased clothing requirements relative to time of stay in the cold atmosphere Moreover the winter comfort zone as defined by the American Association of Heating and Ventilating Engineers shows a decrease of some 5 F in winter temperatures compared with the summer level Healthy individuals following infancy are remarkably tolerant to acute exposures in cold air or water in the benign range of temperature and living in relatively cold rooms (60 to 65 F) has been consistent with good health and not attended by the respiratory difficulties associated with an indoor air environment of 80 to 85 F during the winter season

Immersion Hypothermia It is convenient to divide responses in cold water immersion into three stages (1) stimulatory—deep body temperature (DBT) normal to 35 C (95 F) (2) depressant—DBT 35 to 30 C (3) critical—DBT 30 to 25 C (86 to 77 F) Apparently 30 to 25 C may be a critical zone since it is possible to cool small animals to 0 C (Andjus and Smith)

Cardiovascular Responses With respect to cardiovascular responses of individuals immersed up to the neck in cold water (5 to 15 C) the initial vasoconstriction is followed by a slight rise of rectal temperature and a transient rise in blood pressure and heart rate The heart rate then decreases in response to the action of low temperature on the pacemaker In contrast with the bradycardia associated with the inhalation of oxygen at normal or at high pressures bradycardia due to low temperature is not abolished by atropine or vagotomy Bradycardia is a striking response to hypothermia

At rectal temperatures of 30 C (86 F) arrhythmias may appear and auricular fibrillation is common When the deep body temperature reaches a level of about 25 C (77 F) there occurs in the dog

which render routine therapy inadequate and to be acquainted with the benefit and promise of spasmolytic agents and procedures and of judicious ambient temperature regulation In addition there emerge three important admonitions

1 Avoid trauma to the cold extremity including tight dressings manipulation and massage

2 Leave blisters intact

3 Observe absolute conservatism in any surgical procedure calling for amputation

Sequelae of Frostbite Injury Of the 5 600 cold injury casualties evacuated from Korea during the winter 1950–1951 it was possible for Blair Schatzke and Orr to report on a follow up of 100 patients 4 years following injury Although 90 per cent were gainfully employed about 50 per cent were in some measure handicapped Signs and symptoms associated with mild to fourth degree injury were cold feet (in winter) pain numbness excessive sweating abnormal color and impairment of joint mobility The physical findings in patients who had a diagnosis initially of third and fourth degree injury were scars tissue loss and abnormal nails With the exception of hyperhydrosis the chronic injury may be similar to that produced by ionizing radiation Specific roentgenologic changes in bone were cystlike defects near the joint surfaces in the fingers and toes

It should be emphasized that although the physical findings were negligible following first and second degree injury the pain sweating of extremities and paresthesias were as intense as in the severely injured patients The symptoms in these cases may be looked upon as real not psycho compensatory but it would require refined functional tests to elicit abnormalities in these individuals

Prevention of Cold Injury The painstaking indoctrination and training of personnel and the excellent equipment now available should minimize future cold injury in American military units Emphasis is to be placed however on the elimination of individuals susceptible to cold injury and especially on the "hardening and disciplined training possible only in cold environments Although adaptation requires perhaps a period of several generations to confer on inhabitants of Patagonia the ability to exist with little protection in subzero weather nevertheless the degree of acclimatization possible over a period of months through proper training and graded exposure to cold should render resistant individuals who would otherwise become casualties The nature of cold disability *makes prevention mandatory* There is no specific treatment as yet for the mass disorganization and even disintegration of the biologic economy brought about by cold

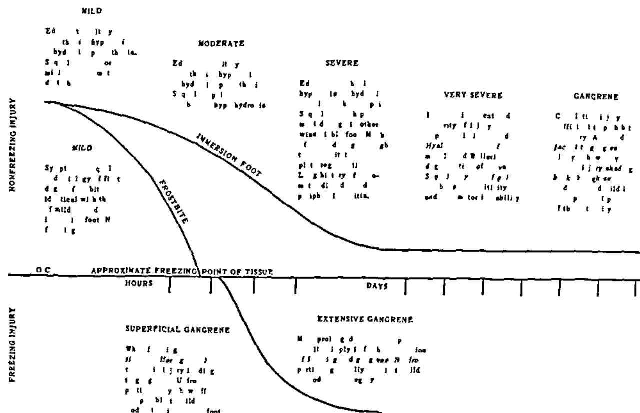

FIG 135 Time temperature relationship in clinical cold injury

is about 8 C (46 4 F) Under these conditions intense vasoconstriction renders the toes exceedingly painful and it is highly probable that the subsequent paresthesia of the feet described as burning sensation which may persist for several years without functional impairment is the result of the ischemia induced during exposure by vasospasm

Frostbite In true frostbite in contrast with immersion foot blood vessels may be severely or irreparably injured the circulation of blood ceases and the vascular beds of the frozen tissue are occluded by agglutinated cell aggregates and thrombi The *cutaneous injury consists in part of a separation* of the epidermal dermal interface From his experiments Kreyberg makes the distinction between direct injury to cells caused by cold which may not be irreparable (if rapid rewarming serves to shorten the duration of the exposure to cold) and the subsequent fulminating vascular reaction *and stasis which precede tissue necrosis* In the therapy of frostbite medical and surgical measures to relieve vasospasm and restore circulation are of prime importance Rapid rewarming may be the method of choice with due concern for the initial elevation of DBT It would appear to serve no useful purpose to heat a cold extremity if the vascular bed cannot accommodate an adequate blood supply In small animals whose extremities have been rapidly cooled to extremely low temperatures within a matter of minutes rapid rewarming is the method of choice when ice crystals are present in tissues It has not been proved convincingly to be so in soldiers whose feet have been exposed to wet cold over a period of *days at freezing* and non freezing temperatures

With *respect to therapy* Korean *experience* interdicted smoking made bed rest mandatory prescribed antibiotics vitamins and nicotinic acid (100 mg t i d) An intravenous frostbite solution consisting of 12 ml ethyl alcohol 250 mg procaine *hydrochloride and 5 per cent glucose in water to* make 250 ml was given every 6 hr To this solution 100 mg heparin was added before administration in the absence of bleeding injury Of the vasodilator drugs hexamethonium was the most effective

One might conclude pessimistically that except *for terminating* the cold exposure promptly and providing good supportive care and later medical and surgical treatment little of value can be done in treating cold injury Yet it is necessary to recognize the type and underlying derangements of the cold injury one is confronted with to be aware of the fact that cold injuries produce a galaxy of ever changing physiologic and pathologic states

to compress the rib cage to a volume that is progressively less forces blood and tissue fluid into the alveoli

The difficulties projected by unequal pressure are seen further in an individual under water who is breathing into a tube opening above the water surface The relative "negative" pressure in the respiratory tract under these conditions is conducive with prolonged respiration to the development of pulmonary edema in much the same process as takes place during the course of edematous obstruction of the trachea from irritant gases or other causes

Effect of Pressure Differences on Ears (Aerootitis Media) Sinuses (Aerosinusitis) and Teeth (Aerodontalgia) In a similar manner aural and sinal membranes are injured by a "squeeze" if the corresponding ostiums of the lined spaces do not permit the free ingress of air In diving operations inability of the auditory tubes to accommodate rapidly to pressure changes occurs in about 10 per cent of apparently healthy individuals About 1 5 per cent of individuals experience sinal pain and another 1 5 per cent are subject to pain in teeth in which the pulp is diseased presumably from bubbles which form more readily in inflamed tissue and which exert pressure

The most common cause of failure to accommodate to increased barometric pressure is infection of the upper part of the respiratory tract with the result that swollen lymphoid and other tissue acts to seal the openings of the auditory tubes and less frequently the sinal meatuses With reference to the ear the pain may be felt over the mastoid area as well as in the auditory canal indicating that the entire membranous lining of the middle ear and mastoid cells is involved The varying degrees of barotrauma in the middle ear may be observed by otoscopic examination of the tympanic membrane to reveal (1) injection of the membrane (2) injection with hemorrhage (3) gross hemorrhage and free fluid in the middle ear (4) rupture of the membrane which requires a difference in pressure of the order of 250 to 500 mm Hg Complications of suppurative *otitis media* moreover are infrequent if the traumatized tissues do not come in contact with contaminated water Spread of infection from the nasopharynx by air passing into the auditory tubes during compression is not established

Effect on Hearing Following acute trauma the audiogram reflects diminished perception of sound over the whole frequency range As the pathologic condition undergoes resolution hearing returns usually to the initial level of acuity This absence or rarity of proved cases of deafness from barotrauma stands in contrast to the permanent deafness from gun fire injury

Overdistention of the Lungs (Traumatic Air Embolism) Ascents have been made routinely in submarine escape training tanks from depths of 100 ft During such ascents the compressed gas in the lungs and in the breathing bag escapes through a relief flutter valve such that intrapulmonic pressure is permitted to approximate the ambient hydrostatic pressure If the individual, however holds his breath during ascent the intrapulmonic pressure will become greater than the hydrostatic pressure and will overdistend the lungs rupturing alveolar sacs and blood vessels Gas thus may be forced or aspirated into the blood stream giving rise to symptoms referable to the circulatory and central nervous systems

Spontaneous Pneumothorax During rapid decompression either with or without air embolism *spontaneous pneumothorax may* occur in the distended lung

Overdistention of Abdominal Viscera In ascent from deep diving depths the expansion of gas previously swallowed under pressure in the stomach and segments of the large bowel is a restraint to further decompression A viscus once having been distended by gas appears to lose much of its propulsive motility In distention of the stomach for example the cardiac and pyloric sphincters become spastic and prevent elimination of gas

SECONDARY PRESSURE PHENOMENA INDUCED BY INCREASED GAS PRESSURES

The phenomena previously described have arisen primarily from differences in pressure which have acted to distend and rupture blood vessels and membranes lining closed spaces On a wholly different basis are those pressure phenomena associated with disturbances in gaseous equilibriums

Narcotic Action of Nitrogen When the air pressure is raised to 4 atm or higher gaseous N induces a narcotic effect shown by decreased neuromuscular coordination and changes in mood frequently euphoria The responses are similar to those associated with hypoxia or alcoholic intoxication Although all individuals are to some extent narcotized at deep diving depths stable individuals apparently react to the stress by increased volitional effort and carry out their tasks until consciousness is lost The unstable individual on the other hand is incapable of purposeful effort

The substitution of helium for N diminishes the narcotic effect of high air pressures In contrast with aquatic animals however symptoms attributable to high partial pressure of gases may completely incapacitate the individual

It is of interest that rare gases such as xenon which are chemically inert are nevertheless capable of producing surgical anesthesia when administered

106 DISORDERS DUE TO ALTERATIONS IN BAROMETRIC PRESSURE

Albert R Behnke

These disorders although of prime military interest are also of direct concern to physicians *dealing with problems arising from air transport* residence at high altitudes or tunnel operations In recent years increased participation in skin diving (i e with self contained breathing apparatus) constitutes a further hazard to several million young persons With increased knowledge of the action of environmental (ambient) oxygen (O) particularly as a regulator of hematopoiesis and its utilization at normal and increased pressure with the realization that one of the toxic manifestations of O administered to premature infants is retrolental fibroplasia with the need to utilize in experimental work various gases under controlled conditions of temperature and pressure with the breakdown of the distinction between civilian and military in defense problems and finally with the knowledge that nascent gas bubbles (in contrast with gas accidentally aspirated into the veins) simulate a variety of pathologic states there is need for the physician to be cognizant of the physiologic changes associated with alterations of barometric pressure

PRIMARY PRESSURE PHENOMENA

Hydrostatic and Gaseous Pressure Adaptations in Aquatic Animals That pressure itself is without injurious effect to life is evident from the fact that aquatic animals exist in a pressure environment of 100 atmospheres (atm) or more Similarly if care is taken not to injure the swim bladder by rapid decompression, greatly increased water pressures will not impair the marine organism The diving mammals illustrate particularly this facile adjustment to pressure alterations A point of further interest in connection with aquatic animals is the *clear cut separation between the effect of the hydrostatic forces per se* and the action of partial pressures of gases Moreover in the swim bladder of the fish one is confronted with the amazing phenomenon that the pressure of gases such as N and O may be many atmospheres higher than the partial pressure of these gases within the tissues of the fish

Effects of Pressure Applied Equally to All Parts of the Human Body Divers have been compressed to almost 18 atm (equivalent to a diving depth of almost 550 ft) without demonstrable damage from the compressive force itself provided that air has free access to all surfaces of the body e g the membranous linings of the middle ear mastoid air cells frontal and ethmoidal sinuses In this connection it should be noted that although the absolute cerebrospinal and blood pressures are increased by 18 atm the manometer recordings of these pressures may not be altered by as much as 1 mm Hg Therefore in so far as the pressure forces operate the brain is not in a "closed box" but is subject to the same compressive forces as *is the skin Similarly a decrease in ambient air* pressure to 0 12 atm (equivalent to an altitude of about 55 000 ft) will not in itself cause injury

Only equal distribution of pressure however preserves unaltered the structure of tissues and the body as a whole

Effect of Unequal Pressure Application (Barotrauma) If the pressure is not equally distributed over all body surfaces a pressure difference between the ambient atmosphere and tissues of more than about 50 mm Hg [1 lb per sq in (psi)] will distort tissue and induce congestion edema hemorrhage and pain *Barotrauma produces a condition* known as squeeze A pearl diver for example is subjected to an additional compressive force of 1 atm for every 33 ft of depth and at 100 ft the total pressure acting on his body is of the order of 4 atm The air in the divers chest at the surface (approximately 6 000 ml) is compressed at this depth to one fourth the surface volume or 1 500 ml (the normal residual air volume') Should the diver descend deeper hydrostatic pressure acting

hypothermia the O_2 in physical solution when pure O_2 is inhaled will meet tissue requirements without the need for hemoglobin as an O_2 carrier These and other similar investigations should greatly extend the scope of O_2 therapy in the treatment of acute critical conditions if facilities become available

Effect on Erythropoiesis It has been shown by Tinsley et al that O_2 breathed by normal persons in concentrations of 50 to 70 per cent (0 5 to 0 7 atm) depresses erythropoiesis (decreased utilization of radioactive iron) in patients with chronic hemolytic anemias pernicious anemia and sickle cell anemia In the last condition the highly active bone marrow is particularly responsive to the depressive effect of the raised O_2 pressure This topic will be developed further in connection with comments on the effect of low O_2 pressures

Fire Hazard The imminent danger of incineration when O_2 is employed makes mandatory meticulous precautions in handling

Carbon Dioxide The augmented cerebral blood flow in the presence of increased alveolar and blood CO_2 tensions explains in large measure the enhanced toxic action of inhaled O_2–CO_2 mixtures and also the enhanced narcotic action of N_2 during the tissue uptake period Indeed the cerebral vasodilatation and increased blood flow associated with the inhalation of atmospheres rich in CO_2 increases the effect of any ambient gas pressure

Tolerance to High Concentrations For submarine operations increased partial pressure of CO_2 in air is considered to be 21 mm Hg for periods not longer than 72 hr Individuals in good physical condition may be exposed to a partial pressure of 36 mm Hg (5 per cent) for periods up to 60 hr This is an upper limit which may be lower for men in a state of chronic fatigue Schaefer has reported evidence of central nervous system depression following the prolonged inhalation (several days) of 2 to 3 per cent CO_2–air mixtures There are so many physiologic variables in the CO_2-tolerance problem that generalizations cannot be made However toxic symptoms attributable to CO_2 are at the low level of injury and appear to be readily reversible There have been no truly long experiments (several months duration) to indicate whether or not real acclimatization to the high CO_2 environment takes place e g the decreased sensitivity to high concentrations of CO_2 mirroring the greater sensitivity to CO_2 observed in residents at high altitude

DECOMPRESSION SICKNESS

Of all the debilities incident to abnormal pressure environments those pertaining to rapid decompression of divers and caisson workers or in the case of the aviator change from normal pressure to substratospheric altitudes are perhaps the most dramatic All persons under these conditions are exposed to acute and possibly chronic injury from nascent gas bubbles principally from those forming in the blood stream and producing intravascular shutting off of circulation to and within important organs Without recompression which forces the free gas into re solution death supervenes within a matter of minutes

Not only are the injuries characteristic of decompression sickness of intrinsic interest but they also simulate a variety of clinical conditions e g shock arteriosclerosis of the terminal aorta involving lumbar segmental arteries and tabes dorsalis Even infection with its pain weakness malaise fever and sweating may be simulated by this condition The nascent gas bubble is replacing the spirochete as the "Great Imitator

A comprehensive monograph on the subject has been assembled by the National Research Council (John Fulton) There is also a recent publication on submarine medical practice prepared by the U S Navy as well as a comprehensive report of proceedings "Underwater Physiology Symposium published by the National Research Council

Death from decompression sickness has been reported following rapid ascent to high altitude in jet aircraft Likewise injury to the spinal cord incident to altitude decompression heretofore considered rare or nonexistent has been described by Haymaker

Regional signs and symptoms of decompression sickness may be tabulated as follows

Table 88 REGIONAL SIGNS AND SYMPTOMS OF DECOMPRESSION SICKNESS

Central nervous system	Cardio-respiratory system	Extremities	Skin
Hemiplegia	Substernal distress	Pain (bends)	Pruritus
Spastic mono- or paraplegia	Paroxysmal coughing on deep inspiration	Numbness	Mottling
Hyperesthesia	Shallow rapid respiration	Weakness	Rash
Anesthesia	Asphyxia	Infarction of bones	Pallor cold sweating
Scotoma	Shock		
Diplopia	Circulatory insufficiency		
Ménière's syndrome			

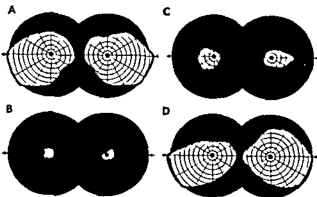

Fig 136 Perimetric measurements made before and after inhalation (3 5 hr) of oxygen at 3 atm pressure (*Behnke et al Am J Physiol* 114 436 1935)

in high concentrations at normal barometric pressure

Oxygen *Toxic Effects* Since the time of Paul Bert it has been known that O induces convulsive seizures in lower animals at pressures of 4 atm or higher Oxygen inhalation by man at the same pressure produces syncope in some individuals and seizures in others Electroencephalographic tracings taken under these conditions may be similar to those found in epileptic patients

At 3 atm pressure seizures do not usually occur The inhalation of O may be well tolerated by healthy adults for a period of several hours During the fourth hour of O inhalation there may occur a rise in blood pressure increase in pulse rate extreme pallor and periodic waves of nausea Of particular interest and further evidence of the intense generalized vasoconstriction is contraction of the fields of vision terminating in amblyopia followed by recovery when air is again inhaled (Fig 136) This is of interest in connection with retrolental fibroplasia experimentally produced in lower immature animals exposed to high concentrations of O It follows that the concentration of O administered to premature infants must be limited to a tension of 300 mm Hg (about 40 per cent of 1 atm approximately 20 per cent less than the generally accepted safe level of 60 per cent given to adults) in order to provide a wide margin of safety

Following prolonged exposure (4 to 6 weeks) to O pressures of 0 7 to 1 atm there may develop in rats pulmonary arteriolar lesions (thickening and hyalinization leading to thrombosis) and later degenerative lesions of the large arteries of the lungs Pertinent is the fact that the obliterative vascular changes are followed by a rise in pulmonary pressure enlargement of the right ventricle and a fall in systemic blood pressure Similar findings occur in man at high altitudes when there is a "break in adaptation" i e loss of ability to work at high altitude Such inability is associated with obliterative endarteritis pulmonary hypertension (Ayerza s disease) and a secondary erythrocytosis superimposed upon the normal adaptive red blood cell (RBC) response to lowered *p*O (Monge)

Procedures or Substances Which Increase Oxygen Toxicity Exercise markedly lowers the tolerance time for the inhalation of O Thus seizures have been reported at diving depths of 33 ft (+2 atm abs) in contrast to a tolerance time of some 10 to 30 min when O is inhaled by individuals at rest in a pressure chamber i e simulated depth of 100 ft (+4 atm abs) Carbon dioxide added to O also greatly increases its toxicity Disturbed transport of CO when O is inhaled at high pressure does not now appear to be a primary factor The exercise and CO effects may be interrelated The individual response to O inhalation in view of such factors as CO and exercise is understandably highly variable Specific note should be taken of the altered sensitivity of the respiratory centers to CO when O is inhaled

Procedures or Substances Which Decrease Oxygen Toxicity From the investigations of Gerschman Bean and others it is now evident that the following procedures or substances diminish the toxic effects of O at high pressures hypophysectomy thyroidectomy adrenalectomy drug depression of metabolism hypothermia lowered alveolar CO tension —SH compounds and bivalent metals i e Mn Co Mg and C Of special interest are data of Gerschman to support certain radiomimetic effects of O at high pressure

Tolerance to Oxygen Pure O at atmospheric pressure produces substernal soreness It is the partial pressure and not the percentage of O that is important for when the pressure is lowered to 0 25 atm equivalent to 34 000 ft it is possible to continue the O inhalation without symptoms In man (adults) and in lower animals all data agree that O pressures of 400 mm Hg or less (about 60 per cent of 1 atm) are not toxic

Therapeutic and Experimental Employment of Oxygen at Pressures above 1 Atm About 2 ml of O is dissolved in 100 ml blood At 3 atm pressure inhalation of O makes possible a supply of O in solution to tissues without the need for reduction of HbO In the treatment of acute CO poisoning J B S Haldane Pace and others have proved the rationale of utilizing O in pressure chambers by hastening the dissociation of HbCO in the presence of an ample supply of O to tissues

In experiments on animals Brauer has observed beneficial effects of high O in rats whose livers would have been otherwise irreversibly damaged by carbon tetrachloride Furthermore he has eliminated the need for red blood cells as O carriers in the perfusate employed in the isolated rat liver preparation

At atmospheric pressure under conditions of

PHYSIOLOGIC CONSIDERATIONS AND DERANGEMENTS AT HIGH ALTITUDES

Maximal Performance of Partially Acclimatized Individuals (1 to 3 Months) The successful scaling of Mt Everest (29 002 ft) by a British Sherpa expedition in 1953 has been repeated by a Swiss expedition Also three other expeditions have been successful in scaling previously inaccessible peaks in the 26 000 to 28 000 ft range In the K2 (28 250 ft) Italian expedition (Desio) O_2 was used initially but not in the final stage of the climb or the return In the French expedition (Herzog) to the top of Annapurna (26 503 ft) and the German Austrian expedition (Buhl) to the summit of Nanga Parbat (26 660 ft) O_2 was not employed These feats which entail severe hypoxia hypocarbia extreme cold inordinate muscular effort disturbed alimentation and stress reactions to danger represent an ultimate in human endurance Members of mountain climbing expeditions who are not native inhabitants of an area between 14 000 and 18 000 ft altitude may be only partially acclimatized during the usual training period of 1 to 3 months at these terrains Above 18 000 to 20 000 ft there is a critical level or true ceiling above which no further adaptation and acclimatization are possible Natives to the 14 000 ft terrain do not appear to be superior to the recently acclimatized (3 to 4 weeks) mountaineer at altitudes above 23 000 ft Above 25 000 ft (the "death zone") rapid deterioration of the physical and mental state takes place if O_2 is not used hence mountain climbers have only about 10 days at or above this altitude to accomplish their objective

Functional and Morphologic Characteristics of the Native Resident at High Altitude A comprehensive comparison between the native resident of Morococha Peru (14 900 ft) and the native living in Lima (sea level) has been prepared by Hurtado and his coworkers Important differences which characterize the Andean as contrasted with the dweller at sea level (SL) are (1) decreased body weight (5 kg) relative to stature and increased vital capacity (2) increased pulmonary ventilation amounting to about 30 per cent per liter of O_2 consumed (3) decreased alveolar pCO_2 (29 mm Hg SL 39 mm Hg) (4) a greatly diminished O_2 pressure gradient and decreased HbO_2 saturation as shown in Table 90 (5) a lowered blood bicarbonate level proportionate to the fall in alveolar CO_2 such that the pH of the blood of the Andean is within normal limits (6) an increase in hemoglobin (21 Gm SL 16 Gm) and O_2 carrying capacity of blood (despite the low alveolar pO_2) amounting to about 1 9 vol per 100 ml (7) an increase in blood volume of about 20 per cent and (8) an increased size of the capillary bed specifically in brain tissue as demonstrated by Schneider

Table 90 EFFECT OF OXYGEN PRESSURE ON HbO_2 SATURATION

Altitude	Oxygen pressure mm Hg			Per cent HbO_2 saturation
	Tracheal	Alveolar	Capillary	
15 000 ft	84	53	41	80
Sea level	147	99	62	98

Table 91 EFFECT OF OXYGEN PRESSURE ON RED BLOOD CELLS

Ambient O_2 atm	Rabbit 1		Rabbit 2	
	Exposure days	RBC million/cu mm	Exposure days	RBC million/cu mm
0 6	28	3 0	20	3 0
0 4			18	4 2
Normal 0 2	108	5 5	56	6 0
0 1	33	9 0		7 7

Specific Erythropoietic Effect of Low Ambient Oxygen Pressure The quantification of response of erythroid elements to variation in O_2 is exemplified in Campbell's (1926) classic experiments In rabbits exposed in stages to a fivefold variation of either high to low or low to high oxygen pressure there occurred a corresponding change in red blood cells of about 250 to 300 per cent as shown in Table 91

Thus it appears that the ambient pO_2 and in turn tissue pO_2 constitute one of the principal regulators of the level of erythropoiesis The role of the bone marrow pO_2 in this matter is not established

Ability to Work The native at high altitudes performs work more efficiently than the resident at sea level in terms of O_2 consumption per unit of weight blood lactate level O_2 debt and pulse rate Irrespective of the reason for the increased efficiency of the native at a high altitude (perhaps because of less excess fat and better physical condition) he is at least as well adapted to his environment as is the resident at sea level

Summary of Functional Changes Making for Acclimatization (from Hurtado et al) From the consideration of the comparative observations presented it is obvious that the permanent resident

Specific comments will be made only with reference to the cardiorespiratory manifestations and bone lesions

Cardiorespiratory Symptoms and Signs The earliest symptom indicative of bubbles in pulmonary vessels following decompression is a sensation of substernal soreness on deep inspiration which elicits paroxysmal coughing (Behnke) When intrapulmonic bubbles increase sufficiently in number rapid shallow breathing (tachypnea) supervenes (Table 88) In the starch experiments of Binger et al shallow rapid respiration (rate 100) was also observed when appreciable quantities of starch were injected Small numbers of gas or starch emboli have been found to have no effect on respiratory rate

With reference to blood gases and HbO saturation the effect of the embolic obstruction in pulmonary vessels is manifest by increased AV difference hemoconcentration and a remarkably low desaturation of hemoglobin (Table 89)

Bone Lesions The osseous and arthritic lesions are always chronic They are painless and insidious when only the shafts of the bones are involved and are identified as sequelae of decompression in caisson workers *mainly on the basis of occupational* history Because of the industrial compensation problem there has been considerable interest in these lesions and a number of excellent reports (e g Taylor Poppel and Robinson) have appeared

The underlying morphologic change is essentially aseptic necrosis due to the obliteration of the blood supply in the diaphyseal portions of the shafts of long bones or in the subchondral portions of the articular surfaces It is the shaft lesions which are usually asymptomatic The joint lesions may be painful and secondary arthritic changes may develop and present an appearance similar to that of chronic osteoarthritis

Types of Injury in Connection with Skin Diving and the Use of Self-contained Breathing Apparatus This subject is treated in detail in appropriate manuals e g Bureau of Naval Personnel Manual on Submarine Medical Practice Because of the wide participation in this sport by adolescents and young adults the following accidents or conditions which already have resulted in fatalities are enumerated (1) drowning as a result of defective equipment (2) air embolism (overdistention of the lungs) (3) barotrauma (injury to ears sinuses and severe hemorrhagic injury to the eyes due to loss of mask pressure) (4) overexertion hypoxia CO excess N narcosis O_2 toxicity CO poisoning (when compressed air is employed) hypothermia and decompression sickness

Treatment of Decompression Sickness The objectives in treatment are immediate and extended recompression even of several days duration and the judicious employment of O and fluids Such therapy has brought about recovery of divers seemingly *in extremis* To treat the shock syndrome *resulting from too rapid ascent more pressure than* that at ground level may be required The most frequent errors in treatment of decompression sickness are

1 Failure to give treatment to doubtful cases

2 Delayed recompression The longer treatment is postponed the more pressure will have to be applied

3 Failure to treat the serious cases adequately

4 Failure to keep the treated patient near the chamber for a 24 hr period

The watch officers bunk was too small to permit one to lie on his back One was forced to lie on one side and then being wedged in between the bulkhead to the right and the clothes-press on the left to hold fast against the movements of the boat underway Cooking was done on the deck using a gasoline stove gasoline engines propelled the boats and consequently poisoning from gasoline fumes was common One awoke in the morning with considerable mucous in the head and frequently with the so-called oil head" Living in a submarine was like living in a damp cellar since moisture inside the submarine condensed on the steel hull plates which were cooled by the sea water (1912)

The interior of the atomic submarine is pleasant and comfortable Air conditioning special lighting color schemes and interior design conducive to eye comfort and esthetic satisfaction are incorporated into the general plan Comfortable berthing and messing spaces are provided along with toilet and even bathing facilities The recreational outlay includes a library tables for small games a motion picture projector and phonographs! 107 RADIATION INJURY

Shields Warren

EFFECTS OF SUN AND ULTRAVIOLET LIGHT

Injury from sunburn is probably the most wide-spread to which the human race is subject Sunburn commonly does not go beyond erythema sometimes accompanied by slight swelling of the affected skin and is followed in the course of days or weeks by hyperpigmentation Rarely is sunburn sufficiently severe to produce second degree burns although moderate first-degree burns are not infrequent Systemic reactions are usually slight although in more severe cases there may be fever and transient leukocytosis Ultraviolet light may produce sunburn The cornea is particularly sensitive to ultraviolet light and even a brief exposure may lead to keratitis and conjunctivitis Years of continuous exposure to insolation or ultraviolet light leads in other than very heavily pigmented skins to increased incidence of carcinoma either epidermoid or basal cell in type

at high altitudes has certain definite respiratory characteristics which may be interpreted as adaptive mechanism to the hypoxic condition resulting from the low environmental pressure Hyperventilation is one of these characteristics The main favorable effect of this process is a rise in the alveolar pO_2 which is accompanied by a decrease in the alveolar pCO_2 It is also possible that a more uniform ventilation takes place at high altitudes

The hematologic aspects of natural acclimatization to high altitudes are characterized mainly by a polycythemia of an absolute type which is the consequence of an increased rate of activity in the formation of red blood cells and hemoglobin in turn this is associated with a proportional accentuation of the processes related to red cell destruction The equilibrium between production and destruction are maintained at a higher level From the early days of high altitude investigation it has been accepted that the hypoxia in this environment is the stimulating factor responsible for the increased hematopoietic activity which affects only erythroid cells Recently a renewed interest has been placed in the study of the humoral control of erythropoiesis by substances of pituitary hepatic and splenic origin

Of the possible adverse effects of altitude residence mention may be made of increased pressure in the pulmonary artery with enlargement of the right ventricle These changes may develop into the decompensatory derangements of frank pulmonary hypertension and cor pulmonale of Monge s disease By contrast high blood pressure and coronary thrombosis are rarely observed

Acute Exposure to Hypoxia In contrast with the native resident the newcomer to an altitude of 15 000 ft does not have the capacity for work His immediate adjustments are primarily respiratory and circulatory since time is required to effect somatic changes Respiratory alkalosis and disturbed sleep are well recognized phenomena during this initial period The most striking findings however relate to glandular changes and altered glandular function which are accentuated in lower animals subjected admittedly to a severe condition of hypoxia These changes may be enumerated as follows

1 Enlargement principally of the adrenal cortex
2 Increased secretion of epinephrine
3 Increase in blood sugar
4 Decrease in thyroid function equivalent to that resulting from thyroidectomy
5 Decreased gastric motility
6 Loss of fertility degeneration of spermatogenic cells
7 Hemorrhages in the intestines and other organs

Although certain blood changes with reference to hemoglobin content and acid base balance have been studied in detail there remain gaps in the knowledge of the fundamental mechanisms involved when acute compensatory reactions fail Excellent reviews of the present state of knowledge are to be found in the studies of Dill Hurtado et al Van Liere and Monge Aviation medical problems are analyzed in the standard reference books by Armstrong and by McFarland

Chronic Mountain Sickness (Monge s Disease) This disease is manifest by the appearance of vascular congestion and cyanosis impaired ability to work, and the following specific derangements using the values of the healthy native resident at altitude as standard (N) Hemoglobin 25 Gm per 100 ml N 21 Gm per 100 ml (blood hematocrit 80 per cent N 60 per cent) There are a blood volume increase of about 50 per cent hyperplasia and hyperactivity of bone marrow erythroid cells abnormal red blood cell destruction relative *hypoventilation* increased cardiac output electrocardiographic findings consistent with the diagnosis of cor pulmonale and associated with a greater pulmonary hypertension and a lower systemic blood pressure than found in the healthy resident

The symptoms and signs of Monge s disease have much in common with Ayerza s syndrome (erythremia cyanosis dyspnea hyperplasia of bone marrow and sclerosis of the pulmonary artery) which apparently has a multiple etiology and with the findings (pulmonary injury and hypertension) following exposure to elevated O_2 pressure referred to in an earlier section

CONCLUDING NOTES

The author desires to emphasize the necessity for frequent physical examination of individuals engaged in hazardous activities who are subject to impairment from physical agents It is mandatory for example *to examine deep sea divers daily* For this purpose a permanent record of pulse rate (counted for 1 min) and blood pressure taken daily prior to the work of the day usually suffices as a control base line in the evaluation of any given individual Deviation of more than ±35 per cent from the mean recorded values requires extended examination This procedure has prevented disability and fatal accidents

Finally in combating the adverse effects of physical agents or a foreign atmospheric environment it is well to realize that a cooperative engineer is the doctor s best friend To illustrate this point let us compare habitability in a German submarine as reported by an officer in 1912 with living conditions in a present day atomic submarine

O ernight crui es were avoided since they were not only considered highly uncomfortable but unhealthy

The dose of external ionizing radiation delivered within a short period of time required to kill half a given human population is about 400 r However if the region of radiation is restricted to a fraction of the body as in the treatment of cancer several times this dose can be given without appreciable systemic effect and with only localized destruction of cells

While in general the radiation of localized tumor bearing portions of the body can be accomplished without serious harm to the rest of the body there may be minor systemic reactions These reactions have been termed *radiation sickness* in the past and are probably due to absorption of protein split products from damaged tissues The patient may react with anorexia nausea and rarely vomiting these are usually transient and without significant organic change

If the intestines or a portion of them are included in the field of radiation and that radiation is heavy (5 000 r or more such as might be used in treatment of carcinoma of the cervix) there may be some diarrhea due to acute injury of the intestinal mucosa Later there may be partial obstruction resulting from scarring and fibrosis with or without ulceration If the liver is included in any field of radiation receiving above 1 500 r the chance of radiation sickness is increased There are usually no significant alterations in the various components of the body fluids during this sequence of events although a transient increase in amino acid excretion in the urine may occur This type of radiation sickness due to local therapy should not be confused with the acute radiation syndrome which is the result of irradiation of much or all of the body

In sharp contrast to the relatively minor reactions encountered as a result of therapeutic radiation of a portion of the body are the effects of the irradiation of the entire body as for example in a nuclear reactor accident or the explosion of an atomic bomb

The acute radiation syndrome is quite different from the effects of chronic low level radiation on the body although the late results of acute whole body radiation may be quite similar to those of chronic exposure Four phases have been described but they are not constant the acute onset with malaise ranging up to prostration usually lasting some hours a phase of relative well being lasting up to several days a period of severe illness of varying character and duration finally recovery or death Fever may develop early and particularly in the absence of infection is an unfavorable sign

In total body radiation the relative sensitivity of the different body tissues largely determines the clinical character of the response If the radiation is sufficiently overwhelming to damage most cells without regard to their relative susceptibility to injury death usually occurs within a matter of hours or days with no distinctive symptoms or signs other than weakness and lassitude progressing to prostration accompanied by a marked leukopenia More usually however the dose of radiation is not sufficiently great to be immediately lethal so that there is opportunity for the varied sensitivity of the different systems of the body to become apparent

Probably the most sensitive cells of the body are the lymphocytes The precursors of the granulocytes are quite sensitive also so that a leukopenia usually develops within 24 hr after exposure following a transient leukocytosis of 12 000 to 20 000 cells per cubic millimeter The prominence and degree of the leukopenia are roughly proportionate to the degree of exposure and hence are of some prognostic value If the white cell count falls below 2 000 per cubic millimeter within the first few days following exposure recovery is unlikely Owing to the longer life of the red blood corpuscles anemia develops more slowly in spite of the great sensitivity of the erythroblasts but may be severe

Hemorrhagic manifestations referable to the combined effect of thrombocytopenia induced by the radiation increased capillary permeability from damage to the endothelial cells and alterations in the coagulability of the blood probably largely mediated through hepatic damage are of importance In the survivors at Hiroshima and Nagasaki hemorrhages both internal and from body orifices petechiae and ecchymoses reached their peak 5 to 6 weeks after the initial exposure The symptoms and signs due to them are variable depending on the location and extent of the hemorrhage

A severe anemia frequently accompanied by pancytopenia develops after several weeks This is not because of resistance of the erythropoietic tissue itself which is highly sensitive but rather because of the long life of the circulating erythrocytes which delays evidence of the damage to the parent tissue The bone marrow during this stage may show aplasia or hypoplasia in which case the outlook for ultimate recovery is not too good or it may show hyperplasia with delayed maturation

Regeneration may be effective and complete or it may be partial In some instances there is apparent failure of maturation large numbers of young forms proliferating and even crowding the marrow for months afterward

Not only is the leukopenia an evidence of serious damage to the body as a whole but also its existence permits infection to become established Multiple cutaneous abscesses stomatitis and cellu

EFFECTS OF IONIZING RADIATION

All living matter is continuously exposed to minute amounts of ionizing radiation derived from both cosmic radiation and the traces of naturally radioactive materials in the soil and water chiefly isotopic potassium and radium These minute amounts constitute the so called background radiation which is of such low intensity that it exerts no significant effect and rarely integrates to more than 20 r in a lifetime

The r or roentgen is an arbitrary unit based on ionization of air The term *rep* roentgen equivalent physical is used to designate the roentgen as determined by instrumentation it is that quantity of ionizing radiation that yields 93 ergs per Gm as it undergoes absorption in tissue The term *rem* roentgen equivalent man is used to designate the quantity of ionizing radiation which produces an effect in man equivalent to that produced by absorption of 1 r of hard x ray radiation

The Committee of the National Academy of Sciences on the Biological Effects of Atomic Radiation estimates that in any 30 years (by which time parents in the United States have conceived over half their children) the dose of background radiation is 4 to 5 5 r According to their estimates the average accumulated dose to the gonads from medical x rays is about 3 r during the same period The radioactive fall out from weapons testing continued at the present rate is estimated to produce a 30 year dose of about 0 1 r

The permissible level of occupational exposure to radiation set by the International Committee on Radiation Protection is 0 3 r per week However very few persons engaged in radiation or atomic energy work approach this level As a further precaution geneticists have recommended that the total dose received by the gonads of even occupational workers not exceed 50 r prior to age thirty

Exposure to significant amounts of radiation does not occur naturally Radiation may be external as from an x ray tube or internal as from radium poisoning or the administration of radioisotopes such as iodine^{131}

Since ionizing radiation cannot be detected by the senses and since its effects are not immediately apparent special precautions must be taken to protect against it when its presence is known or suspected The chief means of monitoring are photographic film electroscopes and Geiger counters Scintillation counters are of value in special cases

Although there are four general types of ionizing radiation—alpha particles beta particles gamma rays and neutrons—they vary greatly in their biologic effectiveness but their qualitative effects on living cells are similar Along the path of an alpha particle ionization is much denser than along that of a gamma ray while its penetration in tissue is much less than that of the gamma ray As a general rule the more penetrating the radiation the less is absorbed by any given unit of tissue and hence the less the biologic effect This variation in effect is known as RBE relative biologic effectiveness" The response of cells to injury by ionizing radiation does not vary qualitatively with the type of radiation but signs and symptoms vary with the amount of tissue damaged and its location

The *mechanism of action* of ionizing irradiation on protoplasm has not yet been sharply defined That ion pairs are formed is clear and that they may disrupt protein molecules and intracellular enzyme systems is also established The effect is so great as compared to the energy released that one has to assume that multiplication of the injury must occur as in an enzyme system

That hydrogen peroxide or oxidative radicals from water are formed within the tissues or that heat is developed due to localized absorption of energy—these are two among the hypotheses that have been put forward to explain radiation changes

The effect of radiation depends to a considerable degree on the rate at which the radiation is given and on the volume of tissue irradiated In general microorganisms or relatively unorganized cells such as those growing in tissue culture are much more resistant to radiation than are more complex organisms

Shorter lived and hence more rapidly proliferating cells are generally rather more sensitive to radiation than are cells with little or no proliferative activity Thus a granulocyte with a life of 3 or 4 days is far more sensitive than is a cortical pyramidal cell with a life approximately that of the individual in whom it exists Cells in mitosis are much more sensitive to irradiation injury than are resting cells

Experience has shown that human somatic cells are not injured by radiation of very low intensity owing to their regenerative powers While only scattered data exist concerning effects on human germ cells and animal experiments have not yet been conclusive it appears that moderate amounts of radiation are required to produce significant genetic mutations On these bases the level of permissible occupational exposure of the entire body has been set at 0 3 r per week which provides a reasonable factor of safety A single dose of 25 r will cause no significant injury though changes in circulating lymphocytes can be brought about by doses as low as 15 r Some degree of illness is almost constantly produced by a dose of 150 r delivered to the entire body The life span will probably be shortened by a dose of 75 r

have followed the use of relatively large amounts of radioactive iodine In man I^{131} has not induced thyroid tumors even though some of the therapeutic levels have been fairly high However among the thousands of cases treated thus far four cases of leukemia have subsequently developed which exceeds the expected incidence

There is evidence from animal experiments of a shortening of the life span as a result of chronic low level radiation premature aging and lowered resistance to infection seem to play a part in this phenomenon

There is evidence that the accumulation of 1 000 r more or less of total body or nearly total body radiation will shorten the life span in man about 10 per cent

A new source of chronic low level radiation has been added by the advent of atomic energy However such great care has been taken in the use of it so far that the radioactive fall out either from weapons tests or from atomic energy installations is relatively insignificant Radioactive strontium is the chief element for concern in fall-out since its long half life (25 years) its chemical similarity to calcium and its ready uptake by both plants and animals make it the single most dangerous component Radioactive fall out has been distributed by now all over the world by the stratospheric winds and slow settling throughout the atmosphere However if the present level of activity of nuclear testing is continued for about 30 years the average dose to the gonads of the population for that period would be on the order of 0 1 r only and hence negligible Although radioactive strontium has been found in human bone and in various animal tissues it has been well below dangerous levels

Medical Effects of the Atomic Bomb Since the possibility of atomic warfare makes it necessary that every physician be familiar with the general principles of injuries resulting from an atomic explosion some mention will be made of blast and thermal injuries as well as of those due to ionizing radiation even though the former are not strictly within the field of internal medicine

The burst of an atomic bomb in air has been compared to an explosion of 20 000 tons of TNT which releases in addition to mechanical energy an enormous amount of radiant energy in the form of infrared visible and x ray radiation as well as a flux of neutrons In an air burst residual radiation from radioactive fission products of the bomb is not a major problem as very little of the fission products reach the ground at the site of explosion but rather are swept up into the stratosphere where they are greatly dispersed and do not achieve a significant concentration when fall-out occurs

In an underwater burst on the other hand as in the second Bikini test residual ionizing radiation may be a very serious problem not only is there temporary radioactivity in the components of the water from the effects of the neutron flux but in addition the radioactive fission products are mixed in the column of water and cloud resulting from the explosion and are rained back upon whatever is beneath However air blast and thermal radiation are not significant

In an air burst secondary air blast injuries resulting from falling structures and flying debris are frequent and varied and range from severe crush to minor lacerations On the basis of Japanese experience crush injuries will predominate with a high incidence of less significant but painful and disabling accidents from flying glass fragments Primary air blast injuries may be largely discounted Any person sufficiently close to the center of an atomic explosion in air to have received primary air blast injury would have received also a lethal dose of ionizing radiation and probably would be fatally burned in addition

The burns received from the thermal energy liberated are of two types flash burns and flame burns Flash burns result from the direct heat of the bomb explosion itself The burns are sharply demarcated and usually restricted to exposed areas of the skin varying in intensity from severe to slight according to the distance from the point of explosion In Nagasaki some flash burns developed in persons up to 2 miles from the hypocenter Flame burns are due to the fires incident to the explosion of the bomb and are in no way different from those commonly encountered Both these types of burns should be treated as comparable burns from non atomic sources would be treated

The ionizing radiation received from the bomb burst is almost instantaneous in character and as already stated a dose of 400 r over the total surface of the body is sufficient to cause death of about half the exposed population

The first symptoms to appear are nausea and vomiting shortly followed by diarrhea Fever accompanies the more severe cases Those receiving heavier doses of radiation (1 200 r or above) will die within 1 to 30 days in spite of treatment

In the cases that survive the first few days signs and symptoms referable to effects upon the more sensitive tissues of the body will be more clearly defined Phagedenic ulcers and septicemia may develop as a result of the destruction of white blood cells and their precursors About this same time or up until 6 weeks later hemorrhagic manifestations appear they are due to damage to megakaryocytes interference with the heparin antiheparin balance of the blood and increased capillary permeability

In some of those surviving beyond 6 weeks a gradually developing pancytopenia appears which eventually leads to death Bone marrow biopsy may

litis of the neck are among the more obvious developments The pathogenic agents may be a wide variety of organisms including those usually saprophytic Bacteremia is a not infrequent complication and often arises from the intestinal flora

The mucosa of the intestinal tract is relatively susceptible to radiation and is of course in constant contact with a wide variety of bacteria As a result ulceration of the intestinal tract occurs and the severity of the ulceration usually determines the character of the signs and symptoms which may range from slight diarrhea and vomiting to bloody diarrhea or rarely ileus with virtual necrosis of *much of the intestinal wall The mucosa of the* colon is somewhat more sensitive than that of the small intestine

Radiation injury to the skin is rarely seen in total body radiation because in those cases where a sufficient dose has been received to bring about characteristic cutaneous changes death usually occurs before they have opportunity to develop When present ulceration and edema are severe However some degree of erythema or transient epilation may occur Some of the Japanese exposed to the atomic bombs at Hiroshima and Nagasaki were epilated but in none who survived was the epilation permanent

Lymphoid tissue shows initial atrophy but may regenerate completely

The rate of healing of wounds or fractures is not significantly altered by radiation insufficient to impair the blood supply although radiation tends to inhibit phosphatase activity

Some fatal cases show atrophy of the adrenal cortex but significant changes in other endocrine glands aside from the hemorrhages incident to the hemorrhagic diathesis have not been observed The adrenal cortical atrophy may be partly related to the malnutrition resulting from the syndrome

Genetic Effects Transient sterility has been noted in the male but permanent sterility is not to be expected as an aftermath of total body radiation since the sterilizing dose for the testis is close to or above the lethal dose for man In women the sterilizing dose for the ovary is considerably more than the lethal dose so although transient sterility may occur permanent sterility would not be expected in survivors

Ionizing radiation is a very powerful mutagenic agent The effect of radiation in producing mutations is cumulative so it makes no difference from the genetic standpoint whether one receives 150 r at one time or spread out over a period of years For this reason special effort should be made to protect the gonads during therapeutic or diagnostic radiation The Committee on Genetics of the National Academy of Sciences has concluded that 10 r to the gonads of the mass of the population in addition to the background will still be commensurate with the good to be received from other aspects of this irradiation However x ray examinations particularly fluoroscopic examinations should not be carried out more frequently than is necessary Thus a fluoroscopic examination of the abdomen may involve a dose to the gonads of as much as 2 r The additional mutants produced by radiation are of the same general sort as those which occur spontaneously A dose either single or cumulative in the range of 30 to 80 r to the general population would probably double the number of mutations now experienced spontaneously It is assumed that *perhaps 2 per cent of total live births show some* minor or major genetic defect at the present time However our data on human genetics are as yet deplorably small

Treatment Treatment of this condition is in its infancy At present the most satisfactory therapy consists in liberal whole blood transfusions the use of antibiotics to control infection parenteral feeding including the amino acid complexes and the alleviation of such local abnormalities as may develop in the course of the general process Adrenal cortical preparations various vitamins and toluidine blue as an antiheparin agent have been suggested and may have slight value

Effects of Chronic Low level Radiation With the knowledge of radiation available today there is little accidental exposure to chronic low level radiation However it occurred in the past among radiologists and others occupationally exposed Radium poisoning has also appeared in some of those persons who drank or received parenterally water containing radium for its supposed therapeutic value The ingestion of radium in any form is now recognized as highly dangerous Chronic low level radiation may be expected to damage the bone marrow with resultant anemia or pancytopenia not infrequently preceded by a period of moderate leukocytosis and relative or absolute lymphocytosis There is in both man and animals a predisposition of the irradiated tissue to the development of malignant tumors In man leukemia osteogenic sarcoma fibrosarcoma and epidermoid carcinoma have been produced The incidence of leukemia is seven to ten times as high in radiologists as in physicians as a whole or the general population Chronic exposure of the skin particularly of the hands of radiologists has long been known to produce carcinoma Some persons who received irradiation of the thymus in infancy have developed carcinoma of the thyroid in early adult life

The radioactive isotopes used for therapy are so selected that they do not remain long in the body Hence they do not provide long continued radiation In the experimental animal malignant tumors

occur and objects within a radius of 100 ft may be struck Direct contact usually results in immediate death Persons nearby may be injured by the electrical current by burning from heated air or by the concussive force of compressed air

If patients die immediately autopsy findings are limited to burns and generalized petechial hemorrhage If patients survive for a period of days or longer post mortem examination reveals focal necroses of nerve spinal cord or brain involving both neurones and white matter with appropriate glial and vascular reactions

Manifestations Immediately after severe shock patients are usually comatose and apneic although the heart may continue to beat until anoxia leads to circulatory failure Surviving this stage patients are often disoriented and combative convulsions are frequent Blackened charred areas at the points of entrance and exit of the current may appear to be relatively small and well localized After a few days however huge sloughs often involving major blood vessels reveal the true extent of the destruction A frequent finding in victims of lightning is a characteristic lacy network of superficial arborescent burns or lightning prints on the skin These fade within 24 to 48 hr Late effects include various neurologic disabilities visual disturbances and of course the residual damage left by burns A curious finding in many victims of lightning is temporary flaccid paralysis of the lower extremities with loss of sensation so called keraunoparalysis which passes off in 12 to 24 hr This condition is often accompanied by blanching and coldness of the legs and is believed to be a result of severe vasoconstriction Hysterical symptoms are common after exposure to lightning Injuries to peripheral nerve spinal cord and brain often leave symptoms which may be confused with peripheral neuritis and multiple sclerosis The development of cataracts is another late complication

The wide use of electric shock in the treatment of psychiatric diseases (p 363) has led to occasional accidents These have been of two types Sudden death attributed to ventricular fibrillation has been observed in elderly patients with heart disease Fracture of vertebral bodies during the convulsive seizure has occurred this is preventable by the use of relaxant drugs

Laboratory Findings Leukocytosis with many large immature granulocytes in the peripheral blood is common after severe electrical shock Albuminuria is the rule hemoglobinuria has been reported in many cases probably secondary to severe burns Although elevation of cerebrospinal fluid pressure is often mentioned in electrical shock, it is an inconstant finding bloody spinal fluid occurs in some cases as a result of widespread vascular injury

Management Immediate *removal of the victim from contact* with the current is obviously important this should always be preceded by cutting off the source of the current when possible Rescuers should be insulated by rubber gloves or a thick layer of dry cloth or newspapers Many needless deaths have followed ill planned attempts to rescue the body of an individual already dead from electrical shock

Artificial respiration should be instituted immediately if the victim is not breathing The importance of this maneuver cannot be overemphasized In one series of 700 cases of electrical injury (Maclachlan) there were 479 with respiratory arrest of which 323 responded to artificial respiration The majority of patients who respond do so within 20 min but recovery after longer periods of time is frequent enough that manual or mechanical respiration should be continued for a minimum of 4 hr before giving up It has been estimated that a delay of 6 min in the institution of resuscitative measures increases the death rate in electrical shock by 80 per cent

Other treatment is supportive Stimulants should be used with caution during the first few hours because of the tendency of many patients to convulse There is no evidence that the frequently advocated procedure of cerebrospinal fluid drainage is beneficial Survivors of the acute episode often require extensive treatment for electrical burns secondary infection and massive hemorrhage as the devitalized tissues slough

Prevention An awareness of the danger of electricity is the most important factor in preventing accidents Proper insulation of appliances in the home and the use of rubber gloves and dry shoes when working with circuits will avoid disability and death Proper grounding of telephone and radio aerials against lightning should be routine In a thunderstorm the safest shelter is a house with windows and doors closed A closed automobile cave ditch or depression is relatively secure Hill tops riverbanks hedges and wire fences should be avoided Although a tree standing alone is dangerous the center of a wooded area is fairly safe

show aplasia or the marrow may be hyperplastic with impaired maturation

The intestinal symptoms are caused by ulceration of the small as well as the large intestine Some ulceration is due to radiation necrosis of the relatively sensitive mucosal cells some to absence of granulocytes to control bacterial invaders from the intestinal contents

As far as can be judged from the Japanese survivors at the present time the great majority of those exposed who survive the acute stage will return approximately to normal Some cases of leukemia may be expected In those exposed to a significant flux of neutrons cataracts may develop

108 ELECTRICAL INJURIES

Ivan L Bennett Jr

The first human fatality from accidental electrocution occurred in 1879 and was produced by an alternating current of 250 v Since that time continuing increase in household and commercial uses of electrical power has made accidents almost inevitable Injury and death from lightning have been occurring of course since time began

Etiology and Pathogenesis The end result of passage of an electrical current through the human body is unpredictable in the individual case Certain generalizations are possible however and many of the factors that influence severity of injury by electricity are known *Alternating currents* tend to produce tetanization of muscles and sweating (which lowers skin resistance) and *direct currents* produce electrolytic changes in the tissues It has been estimated that alternating is about four or five times as dangerous as direct current fatal electrocution can result from exposure to household circuits of 115 v at 60 cycles

The electrical conductivity of tissues parallels their water content consequently the vascular system and musculature are good conductors whereas bones peripheral nerves and skin offer high resistance The resistance of normal skin is lowered by *moisture* and this factor alone may convert what might ordinarily be a mild injury to fatal shock The *grounding* of the body at the time of contact is important It is well known that a person in water or on a wet surface is more susceptible to electrical injury The *pathway of the current* through the body is crucial Obviously an accident involving passage of current between a point of contact on the leg and the ground is likely to be less injurious than one in which the poles of the circuit are the head and a foot The *duration of contact* influences the outcome Because as mentioned an electrical current can stimulate skeletal muscle to contract a victim who has grasped an uninsulated wire may be unable to release it this is far more likely with alternating than direct currents and accounts in part for the greater danger of alternating circuits Sudden convulsive contraction of muscles can result in fractures of bone sometimes however it throws the individual clear of contact This can lead to additional mechanical trauma if the victim is thrown from a high place

In traversing the skin electrical energy of high tension currents is converted to heat When one considers that electric arcs with temperatures as high as 8000 C may be generated it is not surprising that fourth or fifth degree burns often result The term *electrical necrosis* is probably more appropriate than *burn* for this injury It has been suggested that the immediate damage is aggravated by vasospasm in adjacent tissues

The systemic effects of electricity are incompletely understood but in general low voltage produces ventricular fibrillation and death from circulatory failure and high voltage produces respiratory arrest High tension currents produce cardiac standstill but ventricular function resumes when the current stops and death is presumably attributable to injury of medullary centers Whether this neurologic damage is secondary to vasospasm or to increase in temperature of the brain or whether it is the result of direct injury to neurones is not known

A lightning flash is a rush of electrical energy (about 1 billion v and 20 000 amp) along a path more than a mile long and 18 to 20 ft in diameter The duration of the current is about 0 001 sec When the bolt reaches the earth secondary flashes

occur and objects within a radius of 100 ft may be struck Direct contact usually results in immediate death Persons nearby may be injured by the electrical current by burning from heated air or by the concussive force of compressed air

If patients die immediately autopsy findings are limited to burns and generalized petechial hemorrhage If patients survive for a period of days or longer post mortem examination reveals focal necroses of nerve spinal cord or brain involving both neurones and white matter with appropriate glial and vascular reactions

Manifestations Immediately after severe shock patients are usually comatose and apneic although the heart may continue to beat until anoxia leads to circulatory failure Surviving this stage patients are often disoriented and combative convulsions are frequent Blackened charred areas at the points of entrance and exit of the current may appear to be relatively small and well localized After a few days however huge sloughs often involving major blood vessels reveal the true extent of the destruction A frequent finding in victims of lightning is a characteristic lacy network of superficial "arborescent burns" or lightning prints on the skin These fade within 24 to 48 hr Late effects include various neurologic disabilities visual disturbances and of course the residual damage left by burns A curious finding in many victims of lightning is temporary flaccid paralysis of the lower extremities with loss of sensation so called "keraunoparalysis" which passes off in 12 to 24 hr This condition is often accompanied by blanching and coldness of the legs and is believed to be a result of severe vasoconstriction Hysterical symptoms are common after exposure to lightning Injuries to peripheral nerve spinal cord and brain often leave symptoms which may be confused with peripheral neuritis and multiple sclerosis The development of cataracts is another late complication

PART SIX

Diseases Due to Biologic Agents

Section 1 Basic Considerations

109 AN APPROACH TO INFECTIOUS DISEASES

Ivan L Bennett Jr

The vast majority of human and animal diseases of known etiology are produced by biologic agents viruses rickettsiae bacteria fungi protozoa or nematodes No small part of the past and present importance of infectious diseases in medical practice is attributable to their enormous frequency and the public health implications of the contagiousness of many of them It is also of note however that development in sanitary engineering vector control techniques of immunization and specific chemotherapy have modified the situation favorably While important exceptions remain infectious diseases as a class are more easily prevented and more easily cured than any other major group of disorders

THE PARASITE AND THE HOST

The complex interaction between microorganism and man that results in infection and disease has been subjected to extensive study Much has been learned about the initiation of the process the ways in which microbes produce tissue injury the influence of specific immunity and "nonspecific" resistance of the host and mechanisms of recovery Unfortunately it is not yet possible to transfer in any specific way much of the information thus far acquired to the individual human patient with an infectious disease In a textbook of medicine therefore it seems appropriate to emphasize those general aspects of the host parasite relationship that form a basis for diagnostic procedures that are of importance in deriving therapeutic principles or that help explain the epidemiology of infection and infectious disease This necessitates omitting from these pages discussion of many highly significant and interesting experimental studies controversial issues and theoretic or incompletely established concepts The bibliography at the end of the chapter contains excellent reviews of these important subjects

Infection and Clinical Disease It is well known that microorganisms of different species or different strains of the same species vary widely in their capacity to produce disease and that human beings are not equally susceptible to the disease caused by a given bacterium or virus Furthermore while a specific infectious disease will not occur in the absence of the causative organism the mere presence of the organism in the human body does not lead invariably to clinical illness Indeed it is now obvious that the production of symptoms in man by many parasites is an exceptional event rather than the rule a "subclinical infection" or "carrier state" being the usual host parasite relationship *Disease* in a clinical sense is not synonymous with the presence of the organism or *infection* in a microbiologic sense

Mechanisms of Injury It is customary to refer to bacteria or other microorganisms that are capable of producing disease as *pathogenic* *Virulence* the ability to produce harmful effects in the host is distinguished carefully from *invasiveness* the ability to spread and disseminate in the body For example *Clostridium tetani* is pathogenic and by virtue of its exotoxin highly virulent but it is almost completely lacking in invasiveness These distinctions are valuable in microbiology and experimental pathology but they often mean relatively little at a clinical level in an individual patient Under certain circumstances and in certain anatomic locations mildly "pathogenic" organisms can produce fatal disease or highly "pathogenic" species can dwell and multiply without producing any harmful effect

A few parasites produce *toxins* that account for the tissue damage and physiologic alterations of infection *Hypersensitivity* to components of the parasite is demonstrable in several infections but in relatively few has sensitization been shown to account for the manifestations of disease For a large proportion of pathogenic agents an explanation of their damaging effects upon the host is incomplete or wholly lacking Generally therefore the aim of therapy is to stop multiplication or to kill the parasites with appropriate drugs in diseases caused by toxin producing organisms the use of antiserum (as in tetanus or diphtheria) is the definitive procedure chemotherapy being secondary

The *tropism* of certain pathogenic organisms their tendency to *localize in certain cells or organs* and to produce damage is unexplained in most instances Clinically however the presence of disease in a specific anatomic site or a combination of symptoms referable to certain organs often suggests the identity of the causative organism Similarly in the presence of disease known to be caused by a given agent complicating involvement of other tissues can be anticipated or predicted

Frequently the proper management of infectious disease involves the use of techniques completely unrelated to microbiology or chemotherapy in an effort to support the function of damaged organs Survival in poliomyelitis may depend upon treatment of respiratory failure the management of heart failure in endocarditis is sometimes a greater problem than the eradication of the causative organism and in epidemic hemorrhagic fever or Weil's disease maintenance of fluid and electrolyte balance during the stage of acute renal failure is the important therapeutic objective

Resistance and Susceptibility Many so called "host factors" are known to influence the likelihood that disease will occur if organisms enter the tissues or if infection becomes established to play a determining role in the final outcome—recovery or death

In experimental animals *sex strain age route of infection* the presence of *specific antibody other diseases nutritional state* and the use of such procedures as exposure to ionizing radiation or high environmental temperature or administration of mucin nitrogen mustard adrenal steroids epinephrine xerosin and metabolic analogues can be shown to exert a profound effect upon infection by bacteria viruses and other agents

In man these factors are no less impressive although controlled studies are lacking for many Alcoholism diabetes agammaglobulinemia the nephrotic syndrome malnutrition chronic administration of adrenal hormones chronic lymphedema ischemia the presence of foreign bodies such as bullets calculi or bone fragments obstruction of a bronchus the urethra or any hollow tube agranulocytosis various blood dyscrasias and many other circumstances influence susceptibility to systemic or local infection Furthermore in those instances where the extenuating condition is remediable the probability of recovery is enhanced

Racial differences in susceptibility such as the poor resistance of the Negro to tuberculosis or the peculiar resistance of Negroes to malaria caused by *Plasmodium vivax* are well established in several infections The increased frequency and severity of some infections in children others in pregnant females still other in the aged are familiar clinical facts

Prior contact with an organism whether by active infection or by artificial immunization increases resistance to some infections such as measles and poliomyelitis but seems to have little influence on resistance to others such as gonorrhea and acute coryza

In the chapters that follow the variations in human resistance to specific infectious agents are discussed in detail

Finally it must be emphasized that present knowledge of the factors involved in human resistance and susceptibility extends little beyond an *empirical tabulation of clinically observed relationships* The attractive explanations that have been suggested including changes in physical or chemical activity of phagocytes antibacterial substances such as lysozyme properdin and phagocytin *qualitative or quantitative alterations in serum* proteins disordered metabolism at the cellular level products of tissue injury that influence vascular permeability and several others remain for the most part in the realm of hypothesis

The profound influence of "host factors" upon the infectious process makes it clear however that if our understanding of them ever reaches a point that enables us to control them in a predictable fashion we will enter a new era in the management and control of infectious disease There is no more important and fertile field for investigation in medicine

PATHOGENESIS OF INFECTION

With relatively minor variations the development of an infectious disease follows a consistent pattern The parasites enter the body through the skin nasopharynx lung intestine urethra or other portal and a regular sequence ensues Once established in the host the organisms can multiply and in so doing establish a *local* or *primary lesion* From this site there may be *local spread* along fascial planes or tubular structures such as a bronchus or ureter The next step is *systemic spread* of the microorganisms by the circulating blood which they reach by direct invasion of vessels (a relatively unusual occurrence) or by the common method of being borne in lymph to the thoracic duct and entering the venous system In the blood stream they spread to other tissues and can produce *distant* or *secondary lesions* In infections such as tetanus and diphtheria distant lesions are produced by toxins elaborated at the primary lesion without systemic spread of the parasites The infectious process may terminate in recovery or death at any stage the local lesion systemic spread or distant lesion

The apparent inconsistency of this pattern in clinical medicine is attributable to the fact that *the infection has been recognized as a clinical entity* only at the stage when symptoms are most likely to appear For example pneumococcal pneumonia is a local lesion and the distant lesion pneumococcal meningitis is referred to clinically as a *complication* In meningococcal infections the local lesion a nasopharyngitis is rarely symptomatic and has no status as a clinical entity but the stage of spread meningococcemia and the commonest distant lesion meningitis are clinical enti

ties A rarer distant lesion arthritis is called a complication In subacute bacterial endocarditis both the local lesion in the gums and the stage of spread are insignificant the distant lesion is the clinical disease In a patient who has osteomyelitis a clinical entity a recent furuncle may be referred to as a *predisposing factor* In another patient with extensive furunculosis who develops osteomyelitis the infection in bone may be regarded by the clinician as a complication of the superficial infection The stages mentioned are in no way limited to bacterial diseases the primary lesion of poliomyelitis is intestinal viremia may occur without neurologic involvement or a distant lesion the classic infantile paralysis may be established

Because of established clinical usage and terminology based upon the symptomatic illness that leads patients to seek medical aid the consistency of this general sequence in the pathogenesis of infection is often not recognized However the concept is useful to the clinician and offers some basis for systematizing what may otherwise seem to be a miscellaneous collection of unrelated clinical signs and symptoms

CLINICAL MANIFESTATIONS OF INFECTIONS

So varied are the disorders attributable to infection or infestation of man by lower organisms that generalization about them is difficult The clinical manifestations of infection can duplicate those of diseases of any other etiology On p 72 there is a discussion of certain clinical features highly suggestive of infection including abrupt onset fever chills myalgia photophobia pharyngitis acute lymphadenopathy or splenomegaly gastroenteritis and leukocytosis or leukopenia It is obvious that the presence of one several or all of these features does not constitute proof of the microbial origin of illness in a given patient Conversely serious even fatal infectious disease can exist in the absence of fever or the other signs and symptoms mentioned

While there is no infallible clinical criterion of infection it is still possible to recognize accurately many specific infectious diseases from information obtained by *history physical examination blood count* and *urinalysis* The importance of interrogation about past illness predisposing factors such as alcoholism familial disease exposure to ill persons contact with animals or insects ingestion of contaminated food type and order of onset of symptoms and recent or remote residence in endemic areas is discussed in subsequent chapters for specific diseases and etiologic agents Cardinal physical signs are also described for each entity

It is fitting to acknowledge our ignorance of the mechanisms that produce most of the signs and symptoms of human infection As discussed on p 69 the pathogenesis of fever is poorly understood The physiologic alterations underlying "malaise postinfectious asthenia toxicity" and other common complaints are completely mysterious We have little or no idea about the factors responsible for the leukocytoses or leukopenias that characterize certain infections Why the rash of typhus begins on the trunk while that of another rickettsiosis Rocky Mountain spotted fever begins on the extremities is unanswered It cannot be said that failure to understand the production of these manifestations impairs their clinical usefulness in differential diagnosis but it is probable that understanding would bring with it clues to more accurate diagnosis and better management

DIAGNOSTIC PROCEDURES

When dealing with diseases produced by living agents it is soon evident that confirmation of a presumptive diagnosis or sometimes the first suggestion as to the etiology of illness often depends upon laboratory procedures The availability of a multitude of laboratory tests in the modern hospital has not made it possible to substitute a "routine lab work up for history physical examination and observation of a patient s course Indeed the information derived from these procedures is the only reasonable basis for selecting the tests to be performed by the laboratory

The importance of roentgenographic changes alterations in chemical constituents of the blood and tests of the functional capacity of organs such as the liver and kidney is as great in infectious disease as in illnesses of other etiologies and needs no discussion here The specific procedures for the diagnosis of infectious disease involve *direct demonstration of the causative organism* or *proof of its presence by indirect means*

Demonstration of the Organism In bacterial diseases it is often possible to find the causative organism by *microscopic examination of properly stained preparations of sputum spinal fluid and other body fluids* This simple procedure is often neglected as an unnecessary bother when material is being sent for bacteriologic culture but *it is a* most valuable source of immediate information In many diseases the etiologic agent cannot be cultured (bartonellosis) and in others *isolation is* time consuming (tuberculosis blastomycosis) The diagnosis of meningococcal infection (p 870) by finding the organism in fluid *from skin lesions or in* the buffy coat or the finding of *Hemophilus influenzae* in stained smears of cerebrospinal fluid enables the clinician *to initiate* specific chemotherapy immediately with assurance that the regimen is the proper one

Direct examination of bone marrow is a useful method for demonstrating organisms in some diseases kala azar histoplasmosis and tuberculosis being examples In protozoan (amebiasis malaria) and parasitic diseases (schistosomiasis filariasis) *direct examination of blood feces or urine* is the only specific method for establishing a diagnosis

There are also infections in which the *detection of characteristic cytologic changes or the causative organism itself in smears or histologic sections of biopsy material* can be the quickest method for diagnosis *Tubercles and tubercle bacilli in lymph* nodes or liver biopsy material leprosy bacilli in skin or nasal scrapings inclusion bodies in the skin lesions of varicella or variola and exudate of inclusion blenorrhea "Warthin" cells from the nasal mucosa in measles schistosome ova in punch biopsies of rectal mucosa and the Councilman bodies of yellow fever in liver are examples In addition characteristic histologic changes make it feasible to identify the lesions of chancroid syphilis lymphogranuloma venereum cat scratch disease or viral hepatitis in biopsy specimens Indeed even in diseases where other reliable tests are available diagnosis by histologic examination is sometimes the most rapid method an example being the characteristic muscle lesion of Weil s disease (p 1015)

Special Microscopic Techniques *Dark field examination* of material from genital lesions for the spirochete of syphilis is a well known procedure In several other spirochetal diseases including leptospirosis the dark field technique can be useful but experience in recognition of the organisms is necessary for correct interpretation of findings

Fluorescence microscopy in which the causative organisms can be recognized and identified rapidly by the use of fluorescent antibody preparations (the *Coons technique) has not been applied to general clinical work With further refinement and simplification* it may eventually prove to be extremely useful in diagnosis

Culture and Animal Inoculation Specimens for bacteriologic culture should be collected *before the initiation of chemotherapy* The material to be cultured—sputum pus blood or bone marrow—should be selected on the basis of the suspected infections and the precise cultural techniques employed—media CO incubation anaerobic incubation etc —must be decided upon in a similar fashion

In several infections including Weil s disease rat bite fever certain mycoses tuberculosis and the rickettsioses isolation of the etiologic organism can be made by *inoculation of appropriate material into mice or guinea pigs* This is a cumbersome procedure for routine use but in selected instances it should be employed As mentioned in subsequent chapters many viruses can be isolated by inoculation of appropriate animals This is rarely feasible for ordinary clinical diagnosis and for several agents is hazardous

Facilities for *isolating viruses by inoculation of tissue cultures* are available in a few centers but this method is likely to remain an investigative tool until it can be simplified and adapted to general use at a clinical level

Blood Cultures and Bacteremia Because of the peculiar clinical importance of demonstrating bacteria in the blood stream and because there are varying opinions about optimal timing and sites of sampling for blood cultures it is of practical importance to the clinician to understand something about the mechanisms of bacteremia

Excepting intravascular infections (bacterial endocarditis or endarteritis mycotic aneurysm suppurative thrombophlebitis) the entry of bacteria into the circulation occurs almost invariably through the lymphatic system Consequently when bacteria multiply at a site of local infection in the tissues the likelihood of bacteremia parallels the occurrence of local conditions that favor drainage of lymph from the area to the thoracic duct and eventually the venous blood These factors include the number and anatomic arrangement of local lymph vessels accumulation of fluid and increase in tissue pressure (a prominent feature of the inflammatory response) and exercise or massage of the part

Once bacteria enter the blood they are removed rapidly by the fixed phagocytes of the reticulo-endothelial system in the liver and spleen and by engulfment in polymorphonuclear leukocytes in capillaries especially those of the lung

Clinically bacteremia can be transient intermittent or continuous Many transient bacteremias result from manipulation of infected or contaminated tissues common *examples being instrumentation of the genitourinary tract tonsillectomy dental pro*cedures and massage or surgical incision of furuncles or abscesses In the vast majority of instances the sudden discharge of bacteria into the blood produces no symptoms or at most a rigor and brief fever and the organisms are promptly dealt with by the removal mechanisms already mentioned The great importance of these man made bacteremias is their role in producing bacterial endocarditis (p 970) in patients with endocardial damage

Transient bacteremia accompanies the early phase of many *infections In pneumococcal pneu*monia the typical rigor at onset is a result of transient bacteremia In most cases with localization of the pulmonary lesion blood cultures rapidly revert to negative The poor prognosis assigned to patients with pneumonia who continue to have positive blood cultures is not based upon any danger from the mere presence of organisms in the blood as much as it is upon bacteremia as a re

flection of spreading infection in the lung itself

A sudden single influx of microorganisms into the blood stream may be followed by a shaking chill and fever However there is a "lag period" of 30 to 90 min before the febrile response (similar to the lag in pyrogen fever p 70) During this delay the bacteria are usually promptly removed from the circulation by phagocytosis and consequently a blood culture taken at the time of the rigor may be negative Failure to recognize this sequence led for many years to the idea that chilling after instrumentation of the urethra was the result of some peculiar property of the bladder and even today the term catheter fever" is sometimes employed *Failure to obtain growth in a blood culture taken during a chill does not rule out bacteremia as a cause of the fever* Another frequent effect of transient bacteremia is the production of transient severe leukopenia followed by a polymorphonuclear leukocytosis for a few hours *Peripheral leukocyte counts made during the few hours after a chill may give information that is erroneously interpreted in diagnosis*

Continuous bacteremia is a feature of the first several days of typhoid fever of brucellosis and of intravascular infections such as endocarditis

Blood cultures should be taken at frequent intervals in patients with febrile disease of unknown etiology in general an attempt should be made to obtain blood *before* an expected rise in fever or chill When a patient is suspected of bacterial endocarditis or another of the diseases in which bacteremia is constant two to four cultures daily for 2 to 3 days are more than sufficient to establish diagnosis and treatment in such cases should not be withheld for a longer period

There is no evidence that arterial blood possesses any advantage over blood from the antecubital veins for culture Suspected bacteremia is sometimes mentioned as a contraindication to diagnostic lumbar puncture because of the possible development of meningitis but clinical evidence does not support this idea Culture of bone marrow is occasionally superior to peripheral blood for recovery of organisms in typhoid brucellosis and rare cases of subacute bacterial endocarditis While it is common practice to make pour plates of blood and to quantitate bacteremia in terms of a certain number of colonies per milliliter of blood the results of this rather cumbersome procedure have no diagnostic or prognostic significance and it has no advantage for routine use In typhoid for example the number of bacilli in the blood rarely exceeds 25 to 30 per milliliter and bears no relationship to the severity of illness When blood cultures are taken for diagnostic purposes some should be incubated in carbon dioxide and a sample of blood should also be cultured in thioglycollate broth or some other anaerobic medium Anaerobic cultures are especially important in women with puerperal or postabortal infections

Immunologic Methods These diagnostic methods are intended to supply evidence of past or present infection by demonstrating antibodies in serum or other body fluids by showing changed reactivity of the host (hypersensitivity allergy) to products of the organism or rarely to detect components of the causative organism in the body The reader is referred to standard texts of immunology for detailed discussion of the nature of antigens and antibodies the cellular origin of antibody and the complex interactions of antigen antibody systems Emphasis here is directed toward the interpretation of immunologic tests commonly used for clinical diagnosis

Serologic Tests The finding on a single occasion that a patient s serum contains antibody that reacts with a certain antigen merely indicates that the patient has had previous contact with the antigen or a closely related substance For this reason with rare exceptions the clinical interpretation of serologic tests depends upon serial determinations If the antibody titer is found *to rise or fall significantly* one can then be reasonably sure that the response is a result of recent or current contact with the antigen In subsequent chapters the need for serologic testing of acute phase and convalescent serum is emphasized repeatedly *In any patient with a puzzling illness a sterile specimen of serum should be preserved in a frozen state so that it can if necessary be studied and compared with serum collected at a later date*

Prior contact with an antigen can be the result of past artificial immunization with vaccines interpretation of serum agglutinin titers for typhoid bacilli i often made difficult or impossible by prior immunization The occurrence of the so-called anamnestic reaction" a supposed nonspecific stimulation of antibody formation by an acute illness (e g a rise in brucella agglutinins in a patient with acute tularemia) is now known to result only when the two organisms are antigenically related and rarely presents a serious problem The vibrio of cholera contains an antigen similar to that of brucella and surprisingly high levels of brucella agglutinins have been seen in servicemen immunized with cholera vaccine

The exact methods employed for detecting antibody rises in various infections have been selected empirically on the basis of the ease of performing the test as well as on careful study to correlate the results of the test with other diagnostic criteria in patients Therefore the fact that one agent is detected by a precipitin technique another by agglutination of whole organisms or the production of capsular swelling and still another by complement

fixation is a practical matter of convenience and bears no necessary relationship to the agent the type of infection produced or basic pathogenesis By coating some particulate material such as erythrocytes or collodion particles with antigen derived from a certain organism antibody can sometimes be demonstrated by an agglutination test rather than by some more complex method

Particular properties of the causative organism can sometimes be utilized to devise a simplified clinical test for antibody Two striking instances of this are widely used The ability of influenza and related viruses to clump erythrocytes (see p 1050) makes possible the demonstration of antibody to virus by merely testing the capacity of a patient's serum to prevent the agglutination of red cells by suspensions of virus the so called "hemagglutination inhibition reaction Similarly because many microorganisms possess hemolytic components or toxins the assay of a patient's serum for capacity to prevent lysis of red cells is a convenient and simple clinical test for antibody The antistreptolysin O test in group A beta hemolytic streptococcal infections (p 846) is an example of this

In a few infections predominantly those caused by viruses the only reliable serologic test is a *neutralization* or *protection* test an assay of the protection afforded by the patient's serum against active infection in experimental animals or in tissue culture This technique is time consuming and is *usually performed only in special diagnostic centers*

Some mention of nonspecific serologic changes may serve to emphasize again that clinical laboratory tests have come into use *only because they have been found to correlate reasonably well with clinical findings* In several diseases it has been found often accidentally that there develops serum antibody that will react with antigens derived from sources other than the etiologic agent (which may actually be unknown) Common examples are het*erophil agglutinins in infectious mononucleosis (p* 1151) cold agglutinins in some forms of nonbacterial pneumonia (p 1046) and the agglutination of certain strains of *Proteus* bacilli by serum of patients with rickettsial diseases (p 1051) The outstanding example of a clinically useful nonspecific serologic test is the Wassermann reaction for syphilis This test and its modifications are performed with antigens derived from source completely unrelated to the spirochete that causes the disease Because of their simplicity they are still used in preference to more complicated and admittedly more accurate techniques that utilize the *Treponema pallidum* itself (p 1000)

In summary the results of serologic tests must be interpreted in the light of other information about the patient including such factors as previous immunizations and illnesses the possibility of exposure to chemically but etiologically unrelated antigens and the importance of a changing titer *in serial tests as opposed to a single isolated observation*

Skin Tests Exposure to antigens of certain types by various routes and under circumstances not completely understood often results in the development of *immediate (anaphylactic atopic) hypersensitivity or delayed (bacterial tuberculin) hypersensitivity* (see p 1159 for further details)

Active infection with some but not all bacteria and viruses results in delayed hypersensitivity to the infecting agent in some but not all individuals Clinically the detection of this allergic state is accomplished by intradermal injection of the organisms or some component of them in a sensitive person there will appear induration and erythema at the local site within 24 to 48 hr If an individual is highly sensitive *or if the amount of antigen injected* is excessive there may be extensive local inflammation with necrosis vesicle formation edema regional lymphadenopathy and even systemic manifestations of malaise and fever Antigens prepared in concentrations unlikely to provoke severe reactions are generally available for intradermal testing for tuberculosis leprosy mumps lymphogranuloma venereum cat scratch disease chancroid brucellosis tularemia glanders toxoplasmosis blastomycosis histoplasmosis coccidioidomycosis *and many other infections The immune* reaction to vaccination (p 1061) is also an example of delayed dermal hypersensitivity

The reliability specificity and usefulness of the individual tests differ and are discussed in the chapters on specific infections However certain general principles apply to their use and interpretation

1 They are highly useful in epidemiologic surveys as indicators of the incidence of infection in a population

2 In most individuals dermal reactivity persists *for many years or for life A single positive test* means only that at some past time the individual was exposed to the organism (or a closely related one) Unless supplementary information in the form of clinical findings cultural studies or more specific serologic data bear out the presence of active infection a diagnosis of the disease is not justified

3 The appearance of a positive dermal reaction in an individual known to have been nonreactive a short time before is good evidence of recent infection this is becoming a useful method for detecting early tuberculosis

4 A *negative intradermal test does not rule out past or present infection* For unknown reasons patients with measles Hodgkin's disease or sarcoidosis often develop a state of anergy or inability to react to intradermally injected antigens

In several diseases dermal sensitivity develops after weeks or months of infection an important example of this is acute histoplasmosis (p 991) in which patients can be acutely ill for many weeks without showing a positive skin test The skin test to coccidioidin is always negative in disseminated coccidioidomycosis (p 988) and in far advanced or miliary tuberculosis in elderly patients failure to react to intradermal tuberculin in the usual amounts employed for testing occurs in as many as 10 to 15 per cent of the cases

Intradermal injection of antigens derived from sources other than microorganisms usually produces an immediate "wheal and erythema" reaction which subsides promptly The greatest clinical usefulness of this type of reaction is in the detection of allergy to foreign serums pollens and animal dander (see p 1160) The skin tests developed for demonstrating infestation with helminths (trichinosis filariasis) produce reactions of the immediate type in allergic individuals but the antigens employed are so nonspecific that they are of little use in diagnosis

THE IMPORTANCE OF SPECIFIC DIAGNOSIS IN INFECTIOUS DISEASES

Medicine and Microbiology The diagnostic procedures employed for infectious diseases are no more absolute than those in other diseases they cannot be blindly equated with the science of microbiology The responsibility for interpreting the facts supplied by the bacteriologist immunologist and virologist in the total context of a patient s illness remains that of the physician A positive tuberculin skin test certainly does not indicate that a patient has active tuberculosis The finding of *Candida albicans* (monilia) in a stool culture does not necessarily mean that a patient s diarrhea is caused by intestinal moniliasis The presence of staphylococci in nasal cultures from a patient with headaches does not establish a diagnosis of staphylococcal sinusitis A throat culture containing beta hemolytic streptococci does not rule out diphtheria nor does such a culture establish that a febrile illness in a patient with mitral stenosis is a recurrence of acute rheumatic fever and not bacterial endocarditis A positive serologic test for syphilis may be the first sign of incipient lupus erythematosus The decisions in such matters must be made by the patient s physician

Chemotherapy The next chapter discusses the antimicrobial drugs in detail The impact of chemotherapy upon mortality and morbidity from infection and upon epidemic disease is now a matter of historical record These therapeutic agents however have in no way lessened the importance of specific diagnosis indeed their availability has increased the need for obtaining exact etiologic information It requires but a moment s reflection to realize that the substitution of a prescription for a broad spectrum antibiotic or a quick injection of penicillin for the systematic collection of facts and thoughtful consideration of diagnostic possibilities is fallacious unwise and dangerous Numerous antibiotics with overlapping spectrums are now available dosages for different infections vary widely certain diseases are best treated with combinations of drugs and the drugs themselves are potentially dangerous They should never be prescribed as placebos antipyretics or substitutes for diagnosis In the vast majority of instances where this is done patients recover just as they would if no therapy had been given and the drugs are wasted More important inadequate dosage or the wrong agent given blindly may suppress symptoms temporarily without curing make isolation of the etiologic agent difficult and delay the recognition of the true nature of an illness and the institution of curative treatment Finally to expose a patient to the risk of drug reaction without proper indication is inexcusable on the part of the physician whether the drug is an antibiotic a sedative a laxative or a narcotic

Epidemiologic and Other Considerations Just as the decision to administer antibiotics to a patient with a febrile illness of presumed infectious etiology must be made on an individual basis the selection of cases in which extensive cultural and serologic testing is required is a matter of judgment The majority of common "grippelike" illnesses subside spontaneously and symptomatic treatment is sufficient However because of this tendency toward spontaneous recovery and also because the results of serologic tests even if diagnostic may not be available until a patient is convalescent there are many who regard continued effort to determine the specific etiology of illness as an impractical "academic" procedure Such an attitude fails to recognize that the responsibility of the physician extends beyond the individual patient to include the community Furthermore the physician has a responsibility to himself For example a patient recently recovered from "viral pneumonitis" may feel that his physician has cared for him competently and well The doctor himself may feel that he has discharged his professional duties properly and that his having refrained from giving the patient antibiotics for what was clinically a virus disease and therefore unlikely to benefit from chemotherapy was a laudable act of forebearance However if a serologic test is reported a few days later as showing that the patient s serum has shown a rise in complement fixing antibody against psittacosis virus the situation might change The patient himself would continue to be well but a search for

the source of the disease such as the patient's pet parakeet would certainly be indicated and future illnesses in others might be prevented Furthermore the physician would benefit from being reminded that antibiotics are effective in a few of the viral diseases and that pneumonitis is one of the clinical situations in which this possibility should be considered

Other examples of the practicality of academic procedures could be cited There are extremes in everything and in the final analysis the decision about the individual case must be made by the attending physician using his best judgment based on some of the factors that have been mentioned

110 CHEMOTHERAPY OF INFECTION

Louis Weinstein

The *chemotherapy of infection* as discussed in this chapter may be best defined as the use of drugs to suppress the growth of or kill pathogenic microorganisms in the animal body The chemotherapeutic agents at present available for the treatment of infectious diseases can be divided into two main groups on the basis of their origin (1) those which are totally synthetic substances—sulfonamides sulfones quinacrine arsenic compounds and isonicotinic acid hydrazide for example (2) those which are elaborated by various types of microorganisms (some have been synthesized subsequent to their initial isolation)—penicillin streptomycin chlortetracycline (Aureomycin) and chloramphenicol (Chloromycetin) for example The latter agents are classified as antibiotics

THE CHEMOTHERAPEUTIC AGENTS

To be of practical value in the treatment of infection a drug must exert its effect upon the invading microorganism without seriously damaging the cells of the host It is remarkable that so many agents with this selective activity have been developed As far as is known all chemotherapeutic agents exert their effects in the intact animal by acting directly upon the parasite and not by enhancing the natural defense mechanisms of the host The principal action is a retarding of the rate of growth of bacteria (bacteriostasis) which enables the normal defense mechanism of phagocytosis with or without the aid of an antibody to deal with them When present in sufficient concentration some drugs may also kill bacteria in vivo as well as in vitro When certain chemotherapeutic substances are given in large doses early in an infection depression or total elimination of the immune response to the invading microorganism may follow

Quinine emetine heavy metals organic iodides and other synthetic agents are used extensively in the treatment of protozoal and helminthic infections information concerning these agents is presented in the chapters dealing with these specific diseases The discussion to follow will be limited to two classes of chemotherapeutic substances the *sulfonamides* and *sulfones* (effective for the most part only against bacteria) and the *antibiotics* (active against bacteria rickettsiae amebas and some of the larger viruses) Brief mention will be made of two tuberculostatic drugs which are neither sulfonamide compounds nor antibiotics para aminosalicylic acid and isonicotinic acid hydrazide

THE SULFONAMIDES AND SULFONES

The sulfonamide compounds have been used in clinical medicine since 1937 and a number of agents of this type have been developed A few

have been found to be effective in some diseases and relatively nontoxic in man Some of the more important and useful sulfonamides include sulfapyridine sulfathiazole sulfamethazine sulfadiazine sulfamerazine and Gantrisin among those which are rapidly absorbed from the intestinal tract and sulfaguanidine Sulfasuxidine and Sulfathalidine which are poorly removed from the bowel At the present time the most widely used products are sulfadiazine and sulfamerazine and the nonabsorbable Sulfasuxidine and Sulfathalidine

The sulfonamides although less useful at present because of the availability of much more effective antibacterial agents are very valuable in the management of certain infections They are the drugs of choice in meningococcal meningitis and bacillary dysentery They are often applied with varying success in instances of urinary tract infections which have not responded to the use of various antibiotics Sulfonamides are employed in the prophylaxis of recurrent rheumatic fever and urinary tract infection following catheterization These agents are used at times in conjunction with other antibacterial substances in the treatment of severe systemic infections Although there is a strong clinical impression that an additive chemotherapeutic effect may be produced by such a combination data from carefully controlled studies are meager

The sulfonamide compounds at present employed for the treatment of systemic infections are readily absorbed from the gastrointestinal tract and are probably best administered by this route to the conscious patient Preparations for either intramuscular or intravenous use are also available and consist of the sodium salts of the drugs They are much more soluble than the primary compounds and are given most frequently when the drug can not be administered orally In the treatment of meningococcal meningitis intravenous or subcutaneous injection of the first one or two doses of sulfadiazine appears to produce more rapid defervescence than when treatment is initiated by the oral route Liquid preparations made palatable by the addition of flavoring materials are useful in treating young children For most of the infectious diseases in which the sulfonamides are of value the duration of therapy should be no less than 1 week

An adequate concentration of the sulfonamides must be maintained in the blood and tissues to produce effective bacteriostasis A blood level of 10 to 12 mg per 100 ml is sufficient for the management of most of the susceptible infections The interval between separate doses is usually short 4 to 6 hr If the drugs are given by the parenteral route the size of each dose is reduced and the interval between doses increased in order to avoid the development of excessively high plasma levels It is important that the concentration of drug in the blood be estimated at frequent intervals in order that the quantity administered may be adjusted properly this is relatively simple and accurately determined by colorimetric methods

Most of the sulfonamide compounds are widely distributed in the body Exceptions are Sulfasuxidine and Sulfathalidine which are poorly absorbed and largely excreted in the feces After absorption the major metabolic alteration is acetylation of the primary amino group Sulfonamides are excreted by the kidney chiefly by glomerular filtration The distribution of these compounds in the body depends upon the extent to which each becomes fixed to plasma and tissue proteins Derivatives which are not firmly bound tend to be distributed evenly in total body water and thus reach high concentrations in tissue cells whereas those with a tendency to binding are concentrated in the plasma

The bacteriostatic activity of the sulfonamides is presumed to be related to their antimetabolic properties Para aminobenzoic acid (PABA) which inhibits the antibacterial effect of most of these agents is an essential metabolite of microorganisms PABA is part of the molecule of folic (pteroylglutamic) acid It has been suggested that the sulfonamides prevent the incorporation of PABA into the pteroylglutamic acid molecule These drugs probably have other important actions in interfering with the normal metabolism of bacteria They probably do not always act on a single stage in the chain of enzymatic reactions involved in cell metabolism but may inhibit several steps

The principal toxic effects of the sulfonamides are hypersensitivity reactions and injury to the kidneys Hypersensitivity may be manifested by fever rash granulopenia or depression of other components of the bone marrow These reactions may develop any time after the first week of therapy or even earlier in patients who have received the drug previously Sensitivity to one type of compound frequently confers sensitivity to others Damage to the kidney may result from two types of injury (1) precipitation of the sulfonamide especially its acetylated form in the tubules (2) development of a reaction of hypersensitivity in the kidney with the production of lower nephron nephrosis Crystallization of the drug in the renal tubules is most likely to occur when an inadequate quantity of fluid has been ingested or when the reaction of the urine is acid since the solubility of both acetylated and free forms is considerably greater in a neutral or alkaline medium One obvious method of avoiding renal injury is to maintain a copious urine output—at least 1,200 ml per day Another procedure is to produce an alkaline urine by the

oral administration of 12 to 15 Gm sodium bicarbonate per day. With the increase in solubility of the sulfonamide in the urine the excretion of the drug is simultaneously more rapid. The concentration is thus lowered in the blood and this makes necessary the administration of larger quantities in order to raise the blood level to the point of maximal effectiveness. In many clinics, therefore, alkalinization of the urine is not carried out. Another method of preventing precipitation in the urinary tract is to administer two or three sulfonamides concomitantly, since the solubility of each is independent of the presence of the others. This, however, may have a disadvantage since in vitro at least combinations of sulfonamides often exhibit much less antibacterial activity than the drugs used singly. Lower nephron nephrosis, a rare complication of sulfonamide therapy, usually occurs in patients who have taken one of these drugs in the past; it may follow the ingestion of as little as 1 Gm of the agent. It is a totally unpredictable and unavoidable accident for which there is no specific therapy. Another rare but serious manifestation of sulfonamide toxicity is acute hemolytic anemia. This may develop within 48 hr of therapy and is manifested by a rapid fall in the number of erythrocytes, rising icterus, high fever and hemoglobinuria. Drug administration should be discontinued at once and blood transfusions given.

Sulfadiazine (2-sulfanilamidopyrimidine) is absorbed from the gastrointestinal tract slowly and incompletely. Excretion of this agent by the kidney occurs more slowly than with some of the other sulfonamides. It may be recovered in pleural, synovial, pericardial, peritoneal and edema fluids, the tissue concentration being 60 to 75 per cent of that in the plasma. About 50 per cent of the drug is bound to protein but there is no correlation between this and the clinical effectiveness. Only small amounts of the agent are acetylated. Sulfadiazine appears in the urine in both the free and acetylated forms. Neither is very soluble and crystalluria is common. For most types of systemic infection in adults sulfadiazine is administered in a dose of 4 to 6 Gm per day following an initial dose of 4 Gm. In young children 0.065 to 0.1 Gm per lb of body weight per 24 hr usually produces an adequate effect; the initial dose should be about one half of this quantity.

Sulfamerazine (4-methyl-2-sulfanilamidopyrimidine) is absorbed more rapidly and completely from the gastrointestinal tract than sulfadiazine. For these reasons the "loading" dose need be only 2 Gm in most cases and effective blood levels may be maintained by the administration of 1 Gm only every 6 to 8 hr. About 85 per cent of sulfamerazine is bound to plasma proteins. The concentration in the tissues is 50 to 75 per cent of that in the plasma. Very little acetylation of sulfamerazine occurs and the tendency to renal tubular damage and calculus formation is less than with sulfadiazine.

Succinylsulfathiazole (Sulfasuxidine, 2-N[4]-succinylsulfanilamidothiazole) and *phthalylsulfathiazole* (Sulfathalidine, 2-N[4]-phthalylsulfanilamidothiazole) are poorly absorbable from the intestinal tract and are used primarily, therefore, for the suppression of bacterial growth in the intestine. They are usually employed in the preparation of patients for bowel surgery or in the treatment of bacillary dysentery. In the latter disease these agents are generally less effective than sulfadiazine or sulfamerazine.

Gantrisin (3,4-dimethyl-5-sulfanilamidoisoxazole) is more soluble than any of the sulfonamide compounds described above. It is absorbed rapidly from the gastrointestinal tract. About 30 to 35 per cent of the drug is acetylated; this derivative is much more soluble in water than the other sulfonamides in clinical use. The drug is distributed only in the extracellular water of the body and does not penetrate cells. Because of this, the administration of the same quantity of drug will yield a plasma concentration of Gantrisin three times that for sulfanilamide and about twice that for sulfadiazine and sulfamerazine. The clinical effectiveness of Gantrisin is of the same order as that of sulfadiazine. Although smaller quantities were at first thought adequate to produce effective blood levels, more recent experience has suggested that the initial and subsequent doses should be of about the same magnitude as those of sulfadiazine.

Sulfamylon (4-aminomethylbenzenesulfonamide) and *Sulfacetamide* (N-acetylsulfanilamide) are useful in topical treatment of wound and ocular infections.

Elkosin (6-sulfanilamido-2,4-dimethylpyrimidine) is very soluble in urine and favorable results have been reported from its use in urinary tract infections.

Sulfamethoxypyridazine (3-sulfanilamido-6-methoxypyridazine, Kynex) is well absorbed from the gastrointestinal tract and is excreted slowly in the urine. It penetrates the cerebrospinal fluid well and has antibacterial activity about equal to that of sulfadiazine. The administration of a single dose of 3 Gm produces a maximum blood level of 25 mg per 100 ml and the drug may be demonstrable in the urine for as long as 10 to 14 days after a single dose. About 50 per cent of the drug in the urine and 10 to 15 per cent of that in the blood is acetylated. A dose of 1 Gm every 48 hr produces blood levels of 5 to 12.5 mg per 100 ml. Sulfamethoxypyridazine is most useful for prolonged therapy or prophylaxis. The dose recommended for therapy is 1 Gm initially and 0.5 Gm every 24 hr. When higher blood levels are required the dosage can be raised to 2 Gm followed by 1 Gm daily. A weekly dose of 30 mg/kg body weight

has been suggested for prophylaxis against streptococcal infections in rheumatic subjects Blood levels should be determined if therapy is continued for more than 1 week This is mandatory in patients with impaired renal function

Diaminodiphenylsulfone and *Promizole* are sulfones which possess potent antibacterial activity but have the disadvantage of a tendency to cause granulopenia and hemolytic anemia Their use has been restricted largely to the treatment of tuberculosis and leprosy and is discussed in the chapters on these diseases

ANTIBIOTICS

The development of antibiotics for the treatment of infections constitutes one of the most important advances in modern medicine Although a very large number of antimicrobial substances have been isolated from all types of microorganisms plants animal tissues and other sources many have proved too unstable or too toxic to have a clinical application Among those which are clinically useful are penicillin, streptomycin Aureomycin Chloromycetin Terramycin Achromycin erythromycin bacitracin polymyxin and neomycin

Properties of Antibiotics

Antibiotics are chemical substances which are produced by microorganisms and have the capacity to inhibit the growth of and even to destroy bacteria and other microorganisms They are characterized by certain distinct physical chemical and biologic properties which make them ideal potential chemotherapeutic agents for the treatment of infection These properties can be described briefly

1 Antibiotics are selective in their effect on different microorganisms being specific in their action not only against genera and species but even against strains and individual cells Some of these agents act mainly on gram positive bacteria while others inhibit only gram negative ones Others affect alike various types of bacteria regardless of their tinctorial properties Some have no effect upon fungi while others although too toxic to be clinically useful at present, are actively fungistatic Certain antibiotic agents are effective against rickettsiae and a few of the larger viruses The variations in the action of these drugs upon different bacteria and other parasites are both qualitative and quantitative this has led to the development of the concept of an antibiotic spectrum which records the selective action of a given antibiotic upon a number of representative bacteria and other microorganisms

2 The antibiotic agents represent a large number of chemical compounds ranging from simple substances containing only carbon hydrogen and oxygen to more complex forms which contain nitrogen sulfur and even chlorine They vary greatly in chemical structure

3 Certain microorganisms are capable of producing more than one antibiotic *Streptomyces griseus* for example produces streptomycin and mannosidostreptomycin the antifungous agent actidione and the antitrichomonas substance streptocin

4 Some antibiotics are produced by several different organisms Thus various penicillins are formed by different strains of *Penicillium*

5 Salts and serum proteins among other factors may reduce the effectiveness of an antibiotic by neutralizing adsorbing or inactivating it

6 Some antibiotics penicillin for example are rapidly destroyed by various bacteria whereas others such as streptomycin are highly resistant to microbial action

7 The mode of action of antibiotics upon organisms varies Some interfere with growth and cell division Others affect microbial respiration or the utilization of essential metabolites

8 Antibiotics vary greatly in their toxicity for animals and man

9 Most antibacterial agents are potentially capable of eliciting various types of hypersensitivity reactions in patients to whom they are administered

10 Bacteria sensitive to an antibiotic may gradually develop resistance after contact for varying periods Different antibiotics vary greatly in this respect With streptomycin rapid development of insensitivity is common penicillin allows only gradual development of resistance of very few sensitive bacteria

11 The application of antibiotics in the chemotherapy of infections may produce pronounced alterations in the normal bacterial flora of the body especially in the mouth pharynx, and gastrointestinal tract

Modes of Action of Various Antibiotics

Penicillin in low concentrations is bacteriostatic large quantities produce a bactericidal effect Organisms are killed only if they are exposed to the drug while they are in an active phase of multiplication Although the mode of action of penicillin has not been completely elucidated several mechanisms have been suggested The drug combines reversibly with cellular constituents essential for division Derangements of nucleic acid synthesis with decreased formation of ribonucleic acid and desoxyribonucleic acids have also been observed Studies of the binding of the antibiotic agent by organisms have indicated that the more sensitive a strain is the more penicillin is bound without relation to the metabolic state of the bacteria Once bound the drug has the same toxicity for all organisms regardless of their sensitivity

oral administration of 12 to 15 Gm sodium bicarbonate per day With the increase in solubility of the sulfonamide in the urine the excretion of the drug is simultaneously more rapid The concentration is thus lowered in the blood and this makes necessary the administration of larger quantities in order to raise the blood level to the point of maximal effectiveness In many clinics therefore alkalinization of the urine is not carried out Another method of preventing precipitation in the urinary tract is to administer two or three sulfonamides concomitantly since the solubility of each is independent of the presence of the others This however may have a disadvantage since in vitro at least combinations of sulfonamides often exhibit much less antibacterial activity than the drugs used singly Lower nephron nephrosis a rare complication of sulfonamide therapy usually occurs in patients who have taken one of these drugs in the past it may follow the ingestion of as little as 1 Gm of the agent It is a totally unpredictable and unavoidable accident for which there is no specific therapy Another rare but serious manifestation of sulfonamide toxicity is acute hemolytic anemia This may develop within 48 hr of therapy and is manifested by a rapid fall in the number of erythrocytes rising icterus high fever and hemoglobinuria Drug administration should be discontinued at once and blood transfusions given

Sulfadiazine (2 sulfanilamidopyrimidine) is absorbed from the gastrointestinal tract slowly and incompletely Excretion of this agent by the kidney occurs more slowly than with some of the other sulfonamides It may be recovered in pleural synovial pericardial peritoneal and edema fluids the tissue concentration being 60 to 75 per cent of that in the plasma About 50 per cent of the drug is bound to protein but there is no correlation between this and the clinical effectiveness Only small amounts of the agent are acetylated Sulfadiazine appears in the urine in both the free and acetylated forms Neither is very soluble and crystalluria is common For most types of systemic infection in adults sulfadiazine is administered in a dose of 4 to 6 Gm per day following an initial dose of 4 Gm In young children 0 065 to 0 1 Gm per lb of body weight per 24 hr usually produces an adequate effect the initial dose should be about one half of this quantity

Sulfamerazine (4 methyl 2 sulfanilamidopyrimidine) is absorbed more rapidly and completely from the gastrointestinal tract than sulfadiazine For these reasons the loading dose need be only 2 Gm in most cases and effective blood levels may be maintained by the administration of 1 Gm only every 6 to 8 hr About 85 per cent of sulfamerazine is bound to plasma proteins The concentration in the tissues is 50 to 75 per cent of that in the plasma Very little acetylation of sulfamerazine occurs and the tendency to renal tubular damage and calculus formation is less than with sulfadiazine

Succinylsulfathiazole (Sulfasuxidine 2 N[4] succinylsulfanilamidothiazole) and *phthalylsulfathiazole* (Sulfathalidine 2 N[4] phthalylsulfanilamidothiazole) are poorly absorbable from the intestinal tract and are used primarily therefore for the suppression of bacterial growth in the intestine They are usually employed in the preparation of patients for bowel surgery or in the treatment of bacillary dysentery In the latter disease these agents are generally less effective than sulfadiazine or sulfamerazine

Gantrisin (3 4 dimethyl 5 sulfanilamidoisoxazole) is more soluble than any of the sulfonamide compounds described above It is absorbed rapidly from the gastrointestinal tract About 30 to 35 per cent of the drug is acetylated this derivative is much more soluble in water than the other sulfonamides in clinical use The drug is distributed only in the extracellular water of the body and does not penetrate cells Because of this the administration of the same quantity of drug will yield a plasma concentration of Gantrisin three times that for sulfanilamide and about twice that for sulfadiazine and sulfamerazine The clinical effectiveness of Gantrisin is of the same order as that of sulfadiazine Although smaller quantities were at first thought adequate to produce effective blood levels more recent experience has suggested that the initial and subsequent doses should be of about the same magnitude as those of sulfadiazine

Sulfamylon (4 aminomethylbenzenesulfonamide) and *Sulfacetamide* (N acetylsulfanilamide) are useful in topical treatment of wound and ocular infections

Elkosin (6 sulfanilamido 2 4 dimethylpyrimidine) is very soluble in urine and favorable results have been reported from its use in urinary tract infections

Sulfamethoxypyridazine (3 sulfanilamido 6-methoxypyridazine Kynex) is well absorbed from the gastrointestinal tract and is excreted slowly in the urine It penetrates the cerebrospinal fluid well and has antibacterial activity about equal to that of sulfadiazine The administration of a single dose of 3 Gm produces a maximum blood level of 25 mg per 100 ml and the drug may be demonstrable in the urine for as long as 10 to 14 days after a single dose About 50 per cent of the drug in the urine and 10 to 15 per cent of that in the blood is acetylated A dose of 1 Gm every 48 hr produces blood levels of 5 to 12 5 mg per 100 ml Sulfamethoxypyridazine is most useful for prolonged therapy or prophylaxis The dose recommended for therapy is 1 Gm initially and 0 5 Gm every 24 hr When higher blood levels are required the dosage can be raised to 2 Gm followed by 1 Gm daily A weekly dose of 30 mg/kg body weight

therapeutic agents Streptomycin is notorious for inducing resistance Of special theoretic interest is the emergence of a state of dependence upon streptomycin *as a growth factor* In these instances the status of the antibiotic seems to have changed from that of an antibacterial agent to that of a bacterial vitamin This phenomenon has been observed with coliform bacteria gonococci and tubercle bacilli

The development of drug resistance may be the result of selective survival of naturally occurring variants or possibly the production of mutants in the culture The presence of the chemotherapeutic agent does not increase the rate of appearance of these insensitive forms which are at first in such a minority that they escape detection However as the growth of susceptible bacteria is inhibited *the resistant variants multiply and* eventually outnumber the susceptible ones

The acquisition of drug resistance is at present being observed more and more frequently in vivo One of the most important problems in this respect is the increasing number of staphylococci which are insensitive not only to penicillin but also to some of the so called broad spectrum antibiotics (see p 839)

Streptomycin treatment very commonly induces resistance in organisms Some of the bacteria involved in urinary tract infections and *Hemophilus influenzae* for example may become totally insensitive to streptomycin within 3 or 4 days after the initiation of therapy An increasing number of bacteria both gram negative and gram positive have been shown to develop varying degrees of lack of susceptibility to Aureomycin Chloromycetin Terramycin and erythromycin

Organisms which become insensitive to one antibiotic may simultaneously develop resistance to another Thus not infrequently bacteria which lose their susceptibility to Aureomycin simultaneously exhibit insensitivity to Terramycin Chloromycetin and Achromycin The development of neomycin resistance is quite readily associated with a significant loss of sensitivity to streptomycin The reverse does not occur so regularly

Combination of antibiotics may result in a diminution in the speed of emergence of bacterial resistance to any of the drugs in the mixture Organisms exposed to erythromycin alone in vitro rapidly become insensitive if in contact with both erythromycin and penicillin or erythromycin and streptomycin insensitivity to all the agents develops at a much lower and slower rate Clinical experience indicates that the emergence of resistance in the tubercle bacillus to streptomycin may be considerably delayed by the simultaneous administration of para aminosalicylic or isonicotinic acid hydrazide

DETERMINATION OF DRUG CONCENTRATIONS IN BODY FLUIDS

Knowledge of the absorption distribution and excretion of chemotherapeutic agents is of the greatest importance in determining methods of clinical use Sulfonamide and Chloromycetin concentrations in various body fluids can be determined chemically using colorimetric techniques For most of the antibiotics however there is no means of chemical analysis and much more tedious and inaccurate *bioassay methods are required The general* plan of these procedures is to test the body fluid blood urine spinal fluid etc for capacity to inhibit growth of a standard test tube bacterium as compared with the effect of known concentrations of the chemotherapeutic agent

In clinical practice there is relatively little point in *determining the concentration of antibiotic in* body fluids because of the wide margin of error in the bioassay method and because of delay before the results are known Blood levels are sometimes helpful during sulfonamide therapy to warn the clinician when toxic levels are being approached

PENICILLIN

The term *penicillin* was applied by Fleming to a substance produced by *Penicillium notatum* which exhibited inhibitory effect on the growth of certain pathogenic bacteria Subsequent investigation disclosed that the mold produces several penicillins closely related chemically and in biologic activity At the present time only one of them is used extensively in clinical medicine It is called penicillin G or benzyl penicillin or penicillin II The other penicillins have been discarded because of difficulty in manufacture or because they are less effective Penicillin G has been prepared synthetically but the process is very complex consequently the entire supply is still produced by fermentation methods

Now that the drug is available in the form of a *pure crystalline material it would seem preferable* to express dosage in terms of weight but because of established clinical usage it will be difficult to break away from the original arbitrary unit system based upon bioassay Actually 1 000 units is equal to 0 6 mg penicillin G

Penicillin may be administered by several routes orally intramuscularly subcutaneously intravenously or by inhalation It has also been applied topically Application to the skin especially if preparations dissolved in oily bases are employed is to be avoided wherever possible because the degree of sensitization to the drug produced by this type of therapy is very high The procaine salt of the antibiotic is probably the most extensively used preparation because absorption is slowed and

The exact mechanisms by which *streptomycin* inhibits bacterial growth have not yet been elucidated This antibiotic is known however to interfere with normal cell division without disturbing cell growth Streptomycin appears to be capable of disintegrating the cell wall of *Klebsiella pneumoniae* It has been suggested that the drug interferes with the formation of adaptive enzymes in inhibiting respiration Studies of the mode of action of streptomycin on *Mycobacterium tuberculosis* indicate that only the oxidation of long chain fatty acids is sensitive to the antibiotic Some of the metabolic effects of this antibacterial agent are not related to its cytotoxic activity

Chloromycetin affects the amino acid metabolism of sensitive organisms It drastically inhibits protein synthesis as little as 1 to 5 gamma of the drug depresses protein synthesis by *Micrococcus pyogenes* (also called *Staphylococcus pyogenes* through established medical usage) as much as 90 per cent

The mode of action of the tetracycline compounds chlortetracycline (Aureomycin) oxytetracycline (Terramycin) and tetracycline itself (Achromycin) is probably the same for all the derivatives since they exert approximately the same qualitative antibacterial effects and produce cross resistance These agents are bacteriostatic and do not kill organisms directly unless the ratio of concentration of antibiotic to the initial number of bacterial cells is very high The tetracyclines affect oxidation and fermentation in a number of organisms There is strong evidence that they derange nucleic acid formation and protein synthesis

Very little is known about the mechanism of action of other antibiotic agents Phenylalanine or pantothenate causes striking reversal of erythromycin activity Polymyxin E has been found to combine with and probably disorganize the structures responsible for the maintenance of osmotic equilibrium within the cell wall

Testing Organisms for Sensitivity to Various Antibiotics

The sensitivities of bacteria to various chemotherapeutic agents are usually determined by bacteriologic techniques The most accurate method for use in the routine bacteriology laboratory involves inoculation of the organism into culture medium in test tubes containing serial dilutions of the drug After a suitable period of incubation the lowest concentration of antibiotic which inhibits growth of the bacteria is expressed as the sensitivity A more rapid but less accurate method of determining sensitivity involves the use of filter paper disks which have been infiltrated with a known quantity of drug These disks are placed on the surface of blood agar plates on which the organism undergoing test has been streaked The smallest quantity of antibiotic around which inhibition of growth is present is the level of sensitivity of the bacteria This procedure is relatively crude and although useful in clinical practice for the rapid determination of relative sensitivities of organisms does not take the place of the test tube serial dilution technique Wide ranges of values may be obtained for the minimal inhibiting concentrations of any one antibiotic for any given bacterium depending on the method of testing used

Determinations of the sensitivity of an organism to chemotherapeutic agents may be helpful in the management of an infectious disease and clinical laboratories should always be able to carry out such tests reliably They are not necessary in all or even in a majority of cases furthermore there is only a rough correlation between clinical response to a chemotherapeutic agent and the result of the sensitivity test Nevertheless the procedure may be invaluable in indicating which therapeutic agent to employ and the general level of dosage required For example penicillin sensitivity tests on the causative organism should be done in all cases of bacterial endocarditis and systemic infections with *Staphylococcus aureus* or whenever a serious infection is not responding satisfactorily to the treatment given

Resistance of Bacteria to Antibiotics

Each chemotherapeutic agent has a certain range of effectiveness among the various classes of microorganisms Presumably the principal determining factor in this is whether the enzyme system affected by the drug is essential to the existence of a given parasite Another factor is the elaboration by the parasites of substances which inactivate the chemotherapeutic agent For example the *Pseudomonas* group of bacteria which are *naturally resistant to* penicillin produce a penicillinase which when added to a culture medium will inhibit the bacteriostatic action of that drug for organisms normally susceptible to it Some naturally resistant strains of *Staphylococcus* also have been found to elaborate penicillinase Certain bacteria whose growth is not inhibited by sulfonamides synthesize comparatively large amounts of PABA

Acquired Resistance of Bacteria Bacteria growing in the presence of chemotherapeutic agents may exhibit an alteration in susceptibility by virtue of which they become able to grow in concentrations of drug which originally would have suppressed them completely This kind of change can occur within the animal body as well as in the test tube The rapidity with which it develops varies with different bacterial strains and with different chemo

sorbed from the gastrointestinal tract In the treatment of bacterial enteritis—bacillary dysentery for example—the antibiotic is usually administered orally in a dose of 0 25 to 0 5 Gm every 6 hr For systemic infections it is injected intramuscularly at 6 or 12 hr intervals When treatment is required for only a few days 3 or 4 Gm may be given per day large doses should be avoided wherever possible however because of the increased danger of eighth nerve injury Solutions for injection should contain no more than 0 5 Gm per ml since higher concentrations often produce considerable pain Intrathecal administration may be important in the management of meningitis due to organisms susceptible to this antibiotic agent The quantity instilled intraspinally should be dissolved in 10 ml physiologic saline solution this is administered every 12 or 24 hr for 2 or 3 days depending on the clinical situation

Specific indications for the use of streptomycin in various diseases are described in other chapters of this book

CHLORTETRACYCLINE (Aureomycin)

This antibiotic is a product of *Streptomyces aureofaciens* It is a remarkable antibacterial agent because of its wide range of activity encompassing not only many gram positive and gram negative bacteria but also the *Rickettsiae* and some of the larger viruses Many strains of *S aureus* and some of the gram negative bacteria like *Proteus vulgaris* and *Pseudomonas* may become rapidly insensitive to the drug Aureomycin is a basic substance but is usually prepared in the form of a hydrochloride which is strongly acid in reaction The dry salt is stable but in solution it deteriorates rapidly especially if the pH is above 6 Aureomycin is so unstable in the presence of body fluids and in bacteriologic media that definitive studies on its absorption fate and excretion have been difficult to obtain Absorption from the gastrointestinal tract is rapid but inefficient as a result of destruction of the antibiotic by intestinal contents After a single oral dose it can be demonstrated in the urine within 15 min and for as long as 24 hr Concentration in the plasma falls rapidly below detectable level suggesting the possibility of localization and gradual release in some tissue or body fluid Only a small proportion of the quantity injected parenterally can be demonstrated in the urine Aureomycin diffuses into the spinal fluid but in smaller amounts than into the plasma Concentrations of more than 0 2 per cent are very irritating because of the acidity and can cause marked local inflammatory changes with necrosis Subcutaneous and intramuscular injections therefore are not practical Intravenous administration of buffered solutions is possible but there is some risk of phlebitis at the site of injection When the drug is given by mouth nausea and vomiting occur occasionally Attempts to overcome this gastric irritation by the administration of aluminum hydroxide lead to a reduction of the serum concentration of Aureomycin by 80 per cent or more these two agents should not be used together The ingestion of milk or food reduces gastric irritation without altering plasma levels of the drug Mild diarrhea associated with loose bulky stools may be caused by the local irritation or alteration in the bacterial flora of the intestinal tract due to the antibiotic

The dose range of the antibiotic is from 1 to 6 Gm per day given in divided doses at 6 or 8 hr intervals in most clinical infections quantities larger than 1 Gm per day are probably not necessary The dose for intravenous administration is about one third to one fifth as large as that given by mouth

CHLORAMPHENICOL (Chloromycetin)

The initial preparations of Chloromycetin were obtained from cultures of *Streptomyces venezuelae* The drug has been isolated in pure crystalline form and synthesized There is no difference in the antibacterial activity of the synthetic and the natural products The presence of an NO group makes possible a colorimetric method of determination similar to that used for the sulfonamides

Chloromycetin is a white neutral crystalline powder which is stable in the dry state In solutions ranging in pH from 2 to 9 it is stable at room temperature for at least 24 hr It is highly insoluble in water—approximately 0 25 per cent soluble at room temperature—but it is soluble in propylene glycol up to 15 per cent

Most treatment with Chloromycetin is carried out by the oral route although preparations are available for intramuscular or intravenous injection The demonstration that this agent may on occasion depress the bone marrow suggests caution in its administration The drug is rapidly absorbed from the gastrointestinal tract appearing in the blood within a few minutes The maximal concentration occurs at the end of 2 hr but some may still be found after 16 or 24 hr About 80 per cent of the quantity administered orally can be demonstrated in the urine by the colorimetric method however only about 15 per cent is still active according to bioassay Inactivation appears to be due to conjugation with glucuronic acid

A large number of organisms are susceptible to Chloromycetin Although it is active *against some* types of gram positive bacteria it is most effective against the rickettsiae and gram negative organisms *S aureus* coliform bacilli and *other enteric organ*

detectable blood levels may be present for as long as 24 hr The addition of aluminum monostearate to procaine penicillin may allow detectable blood levels to be maintained for as long as 48 to 72 hr Solutions of crystalline penicillin G in physiologic saline may be inhaled for the treatment of various acute or chronic pulmonary infections

Among the more recently developed types of penicillin are Bicillin (dibenzylethylenediamine dipenicillin) and penicillin V (phenoxymethyl penicillin) Bicillin may be administered either by mouth or parenterally When given orally however the absorption of this agent is more erratic than that of buffered penicillin G which yields three to six times the penicillin activity of Bicillin The intramuscular injection of Bicillin has the advantage over penicillin G of prolonging the duration of blood levels the administration of 200 000 to 500 000 units may produce a detectable concentration of antibiotic in the blood for as long as 2 weeks Penicillin V differs from G in a single oxygen molecule The free acid and potassium salt are more stable and much less soluble at the pH of gastric juice than is penicillin G Penicillin V is however rapidly dissolved in alkaline solution and is readily absorbed from the upper portion of the small intestine Taken by mouth penicillin V produces higher and more prolonged blood levels than the same quantity of penicillin G The intramuscular injection of penicillin V produces lower blood levels than penicillin G given by the same route

Only about 20 per cent of an orally administered dose of penicillin G is absorbed into the blood stream the remainder being destroyed by gastric acidity and by penicillinase in the lumen of the intestines As a consequence much larger doses are needed for oral than for parenteral therapy Administration of alkalinizing agents with the drug apparently does not increase appreciably the amount absorbed Penicillin should not be given by mouth later than 1 hr before or earlier than 2½ hr after a meal When penicillin is injected subcutaneously or intramuscularly it causes little or no local irritation and is absorbed very rapidly into the blood stream from where it is either excreted by the kidneys or distributed evenly in the plasma and extracellular fluid Normally only minute amounts penetrate into the cerebrospinal fluid *but in the presence of meningeal inflammation* appreciable levels of the drug may be obtained

Penicillin is excreted by the kidneys with great rapidity mainly by a tubular mechanism about 10 per cent being cleared in the glomerular filtrate The renal clearance approximates the total renal blood flow Attempts have been made to delay renal excretion by concurrent administration of substances which compete for available tubular excretory structures Diodrast para aminohippuric acid and Benemid (*p* di *n* propylsulfamyl benzoic acid) retard penicillin excretion to a variable degree Benemid appears to be the most effective in reducing the rapidity of excretion of penicillin the dose is 0 5 Gm four times a day

Penicillin is almost devoid of toxicity in the human being It does produce however a number of untoward effects many of which are due to the development of hypersensitivity These are discussed in detail below

The clinical use of penicillin in treating specific infections is discussed in detail in other chapters of this book

STREPTOMYCIN

Streptomycin is an antibiotic produced by *S griseus* It is active against both gram positive and gram negative organisms the latter being more sensitive than the former This drug is the most powerful of all tuberculostatic agents

Dihydrostreptomycin is a derivative of streptomycin which is produced by catalytic hydrogenation It has been used in place of streptomycin because it was believed to produce less neurotoxicity However damage to the auditory nerve following dihydrostreptomycin therapy is about as frequent as that following streptomycin provided full doses are employed Streptomycin tends to affect the vestibular portion, while dihydrostreptomycin produces most of its damage in the cochlear portion of the eighth nerve There is evidence that dihydrostreptomycin is as effective as streptomycin gram for gram in the treatment of tuberculosis and all other infections susceptible to the action of streptomycin The dihydro derivative appears to cause fewer reactions of hypersensitivity than streptomycin and can be administered to patients who are intolerant of the latter

Streptomycin is a basic substance and is usually prepared in the form of a hydrochloride or sulfate which is readily soluble in water

Streptomycin salts or dihydrostreptomycin are readily soluble in water The drug is poorly absorbed from the gastrointestinal tract When injected parenterally streptomycin is distributed evenly in extracellular body fluids but very little if any penetrates the blood–spinal fluid barrier *unless meningeal inflammation is present* After a single intramuscular injection approximately 80 per cent of the antibiotic appears in the urine over a period of 24 hr Renal excretion appears to be largely by filtration

There are three routes of administration intramuscular topical and oral Streptomycin is given by mouth when a local effect in the intestinal tract is desired but this route is of no value in the treatment of systemic infections because so little is ab

rapidly Despite the relatively short period of time during which this agent has been used an incidence of 25 per cent of erythromycin insensitive strains of *S aureus* has already been reported from one clinic Because of this it is probably best, in clinical practice not to administer erythromycin alone penicillin or streptomycin should be given concurrently

BACITRACIN

Bacitracin is a polypeptide antibiotic produced by a strain of *Bacillus subtilis* The bacterial spectrum resembles that of penicillin The drug is soluble in water or physiologic saline solution It is most frequently applied topically in various types of ointment For systemic administration it is usually dissolved in 2 per cent Novocain solution in physiologic saline solution

Very little bacitracin is absorbed from the gastrointestinal tract although it inhibits the growth of many bacteria in the bowel including clostridia and gram positive cocci The antibiotic appears in the blood and tissues but very little diffuses into the cerebrospinal fluid after intramuscular injection The renal clearance of the drug is low and approximates the glomerular filtration rate Bacitracin is excreted slowly it is unlike penicillin in that plasma concentrations may remain elevated for several hours

Bacitracin has its greatest clinical application in the topical therapy of infections due to *S aureus* and other gram positive bacteria particularly those resistant to other antibiotics The large number of strains of micrococci insensitive to all the commonly used chemotherapeutic agents occasionally necessitates consideration of parenteral administration of bacitracin in systemic disease The intramuscular dose is 15 000 to 20 000 units given four times a day Larger quantities increase the risk of serious renal damage Careful attention must be given to the development of nephrotoxic manifestations if kidney dysfunction becomes appreciable the drug should be discontinued

POLYMYXIN (Aerosporin)

Polymyxin is a polypeptide antibiotic obtained from *Bacillus polymyxa* The principal effect is upon gram negative bacilli for which it is one of the most potent chemotherapeutic agents available strains of *Proteus* are however resistant The drug can be administered intramuscularly at intervals of 8 or 12 hr the total daily dose being 0 2 to 0 5 Gm It is not absorbed from the bowel but it eliminates sensitive organisms from the intestinal flora Following parenteral use it disappears from the blood quickly It does not pass into the cerebrospinal fluid and cannot be detected in the bile or in the urine in biologically active form Considerable limitation of usefulness arises from its toxicity for the kidney this becomes evident usually on about the fourth or fifth day of treatment in a significant proportion of patients There may be only proteinuria or oliguria, or nitrogen retention may supervene Some preparations of the antibiotic have been found to be relatively free of nephrotoxicity Although not detectable in man antidiuretic activity for animals has been demonstrable in some preparations of polymyxin Because of the danger of renal damage this chemotherapeutic agent should be employed only when others are ineffective and when the patient s life is in jeopardy Impressive clinical results have been produced in some cases of *Pseudomonas aeruginosa* bacteremia and in meningitis due to the same organism

NEOMYCIN

Neomycin is an antibiotic derived from a strain of *Streptomyces* closely related to *Streptomyces fradiae* It is a basic compound heat stable and resistant to the action of acid (pH 2) at the temperature of boiling water It is bactericidal in vitro against a wide variety of gram negative and gram positive organisms There is some indication that it is the most effective chemotherapeutic agent in the treatment of infections due to *Pr vulgaris* The drug has been administered by oral and parenteral routes Absorption from the intestinal tract is relatively poor The result of 2 Gm given by mouth every 6 hr is a concentration of neomycin in the blood one-eighth as high as that which follows the intramuscular injection of only 0 5 Gm every 6 hr The usual oral dose of neomycin is 2 Gm in divided doses per day The antibiotic may also be administered intramuscularly the daily dose is 1 to 2 Gm

Although the in vitro antibacterial effectiveness of neomycin is impressive its clinical usefulness is sharply limited by high toxicity Kidney and eighth nerve damage occur in a significant number of patients In view of these untoward effects neomycin should *never* be the first drug employed in the treatment of any infection It should be reserved for those diseases in which no other antibiotic is effective and the infection threatens life The magnitude of the risk of renal or auditory nerve injury must always be weighed against that of the untreated infection If used critically and intelligently neomycin may occasionally be life saving

NOVOBIOCIN

Novobiocin (Cathomycin, Streptonivicin Albamycin Cardelmycin) is elaborated by both *Strepto*

isms are known to become resistant to this antibiotic

Aside from the mild gastrointestinal irritation produced by Chloromycetin the most serious untoward effect which results is depression of the bone marrow Granulopenia develops first and may be followed by aplastic anemia if administration of the drug is continued this is rare The other complications of Chloromycetin therapy are discussed below

OXYTETRACYCLINE (Terramycin)

Terramycin is an antibiotic produced by *Streptomyces rimosus* It is very closely related chemically to Aureomycin This agent is available for clinical use in the form of a hydrochloride It may be administered orally or intravenously and is relatively stable over a wide range of temperature and pH

The most commonly used form of Terramycin is the capsule of the crystalline hydrochloride salt This is available in 50 100 and 250 mg doses for oral use Intravenous injection of this antibiotic should be reserved for instances of severe illness or for cases in which it cannot be taken by mouth Solutions of Terramycin must be properly buffered and in no circumstances should unbuffered drug be given for any purpose

Terramycin is absorbed rapidly from the gastrointestinal tract No significant difference is present in the plasma concentration when the agent is given in the fasting or nonfasting state A single oral dose may produce detectable concentrations in the blood for as long as 24 hr When 250 mg of the drug is given at 6 hr intervals blood levels are usually in the order of 5 to 10 μg per ml throughout the 24 hr period Intravenous injection produces serum levels ranging between 5 and 10 μg per ml at the end of 1 hr and from 1 to 5 μg per ml after 12 hr

The clinical applications of Terramycin are practically the same as those for Aureomycin There is very little difference in antibacterial activity between these two agents

TETRACYCLINE (Achromycin)

Achromycin is closely related chemically to both Aureomycin and Terramycin It is essentially the skeleton structure of these two antibiotics and is prepared synthetically In vitro tests indicate that the biologic activity of Achromycin is equal to that of Aureomycin and Terramycin It appears that Achromycin is useful in the same infections as are known to respond favorably to either Aureomycin or Terramycin The incidence of side reactions such as nausea vomiting and diarrhea is said to be lower following the use of Achromycin than has been observed with the other related drugs The development of bacterial resistance to Achromycin is accompanied by simultaneous loss of sensitivity to other agents

Achromycin is stable in solution maintaining its activity in solution at 37 C for at least 7 days The drug is available in the form of the crystalline hydrochloride in capsules as a dispersible powder and for intravenous use Intravenous therapy should be employed only in patients who are unable to take medication by mouth The average adult dose is 500 mg intravenously at 12 hr intervals This dosage may be increased to a maximum of 500 mg every 6 hr For oral treatment a dose of 1 to 2 Gm divided into four doses per day is usually adequate

ERYTHROMYCIN (Ilotycin)

Erythromycin is an antibiotic elaborated by *Streptomyces erythreus* It has been produced in crystalline form as a basic compound It is soluble only to the extent of 2 mg per ml in water but it is highly soluble in alcohols and in a number of other organic solvents The drug retains its activity in solution at 4 C for at least 8 weeks at room temperature there is some deterioration during the first week but not for the next 2 months whereas at 37 C decrease of antibacterial activity begins to appear on the fourth day and continues progressively thereafter

The usual route of administration of erythromycin is by mouth the drug is absorbed from the intestinal tract There is a rough correlation between maximal blood level and the dose of antibiotic ingested Peak serum concentrations appear 1 to 2 hr after ingestion of a dose and decline rapidly so that the agent is no longer demonstrable after 4 to 6 hr Only small amounts are recovered from the urine

Gram positive organisms including *S aureus* are highly sensitive to erythromycin being inhibited on the average by concentrations of less than 1 μg per ml

In clinical practice the use of erythromycin should be restricted to the treatment of infections due to gram positive organisms Since penicillin is so highly effective in pneumococcal and beta hemolytic streptococcal diseases and no penicillin resistant strains of these bacteria have yet been discovered erythromycin is not the drug of choice in these infections Strains of *S aureus* which are insensitive to all other antibiotics may be highly susceptible to erythromycin This chemotherapeutic agent is therefore most valuable in the management of disease produced by staphylococci or other penicillin resistant gram positive organisms

Bacteria exposed to erythromycin either in vitro or in vivo become resistant to the drug quite

fying agent has been suggested The development of bacterial resistance to the drug has not been noted

The infections of the urinary tract which respond most favorably to therapy with nitrofurantoin are the acute and uncomplicated ones Infections produced by E coli are the most easily eradicated by this agent Those due to *Ps aeruginosa* are totally unaffected and infections caused by *A aerogenes* occupy an intermediate position *Pseudomonas aeruginosa* may appear in the urine for the first time during a course of treatment with nitrofurantoin Although the drug has been said to be most active against *Proteus* infection the results are quite variable Not infrequently this organism is only temporarily suppressed and reappears after cessation of therapy

Nitrofurantoin is relatively nontoxic Nausea with or without vomiting is the commonest untoward reaction Various types of rashes have been described Although it is known to suppress spermatogenesis in animals when given in large quantities this effect has not been observed in man

TUBERCULOSTATIC DRUGS

Although streptomycin is effective in the treatment of all types of tuberculosis the use of this agent alone leaves much to be desired in the way of maximal antibacterial effect as well as in preventing the emergence of drug resistant strains of *M tuberculosis* For these reasons attempts have been made to develop other compounds possessing tuberculostatic activity which might be employed alone or might be given concurrently with streptomycin Two such agents are para aminosalicylic acid and isonicotinic acid hydrazide

Para aminosalicylic Acid (PAS) Para aminosalicylic acid is a white crystalline powder It is sparingly soluble in water but is easily dissolved in the form of its sodium salt This agent has a bacteriostatic effect in vitro against many strains of *M tuberculosis* even those which have become streptomycin resistant The antibacterial activity is not inhibited by serum or sodium salicylate but is partially decreased by PABA

Para aminosalicylic acid and its sodium salt when given orally are rapidly absorbed and quickly excreted It is necessary to give the drug frequently in order to reach and maintain adequate blood levels A single dose produces maximal serum concentration within 30 to 60 min of administration thereafter there is a gradual fall so that the agent disappears from the blood in 2 to 3 hr The agent attains high concentrations in the interstitial tissues of the pulmonary alveoli in the liver and in the kidney It also diffuses into the cerebrospinal fluid and the pleural cavity The quantities are smaller in tuberculous cavitation than in normal lung Para aminosalicylic acid is almost entirely excreted by the kidney in unchanged or acetylated forms

Para aminosalicylic acid is usually given orally Since considerable gastric irritation may result from the large quantities necessary the concurrent administration of various types of alkali or milk is advisable Various mixtures containing flavoring and alkaline compounds have been employed Preparations for intravenous use are also available these should be reserved for patients in whom severe gastric distress prohibits oral use or for those in coma The usual quantity given by mouth is 8 to 12 Gm per day in divided doses Although it has been reported that PAS alone may be effective in the treatment of mild tuberculous infections it is best to give this agent together with streptomycin The details of this type of treatment are described in Chap 141 Tuberculosis Tubercle bacilli may become resistant to PAS if this drug is used alone Combination with streptomycin delays remarkably the speed of emergence of resistance of the organisms to both agents The other advantage of such combined therapy is the additive tuberculostatic action of the two drugs

The most common toxic effects produced by PAS are nausea vomiting and burning epigastric distress Diarrhea occurs occasionally Toxic damage to the liver and potassium deficiency have been recorded Prolongation of the clotting time of the blood has been noted in patients to whom large quantities (30 Gm per day) have been given the administration of synthetic vitamin K prevents the onset of this prothrombin deficiency and cures it if it has appeared Occasionally tinnitus and reduction in the acuity of hearing may develop they usually disappear rapidly after cessation of treatment

Isonicotinic Acid Hydrazide This is the most recently developed drug which has been used in the therapy of tuberculosis Of all the tuberculostatic agents isonicotinic acid hydrazide has the highest activity in vitro It is not effective against organisms other than *Mycobacteria*

Isonicotinic acid hydrazide is administered orally as a rule and is almost completely absorbed from the digestive tract From one half to three quarters of the amount ingested is recovered from the urine in 24 hr and not more than 5 to 10 per cent appears in the feces The peak serum concentration may occur from 1 to 3 hr after administration and the minimal detectable concentration of 0 4 *µg per ml* persists for 6 to 24 hr This level is higher than that necessary to control tubercle bacilli *in vitro* The drug is well distributed in the various body fluids and is not inactivated by them it is present in sputum urine pleural exudate plasma and cerebrospinal fluid in active form It passes the

myces niveus and *Streptomyces spheroides* It is a dibasic substance the exact chemical composition of which is not known Although the basic compound is insoluble in water and fat solvents, salts formed with metal ions dissolve readily in aqueous solution In vitro the drug inhibits the growth of strains of S *aureus* resistant to penicillin the tetracycline compounds chloramphenicol and erythromycin as well as hemolytic streptococci *Brucella* the pneumococcus the meningococcus *Hemophilus pertussis* *Pasteurella* and *Proteus* There is a marked decrease in antibacterial activity in the presence of serum more than 90 per cent of novobiocin appears to be bound to serum protein The drug is rapidly absorbed from the intestinal tract it may also be given parenterally After two doses of 0 5 Gm each given 6 hr apart the concentration in the blood ranges between 16 and 128 gamma per milliliter This antibiotic is excreted slowly appreciable amounts are detectable in the serum for 24 hr Novobiocin is excreted in the urine

Most investigators have recommended that the use of novobiocin be restricted to the treatment of staphylococcal infections due to strains which are insusceptible to other antibiotic agents because it has no advantages over other drugs when employed for the eradication of other sensitive organisms However *Proteus* is sometimes sensitive to novobiocin and its use has proved effective in infections produced by strains of this organism insensitive to other antibiotics Staphylococci become resistant to novobiocin rapidly For this reason it should never be administered alone but should be given concurrently with another antibiotic to which the infecting strain is sensitive The usual dose of novobiocin is 0 5 Gm at 6 hourly intervals orally or 1 to 2 Gm in equally divided doses intramuscularly Transient nausea and vomiting and dermatitis have been noted following its administration

NYSTATIN

Nystatin (Mycostatin) is elaborated by *Streptomyces noursei* and has an empirical formula of $C_{46}H_{83}N_{18}$ It is a pale yellow substance insoluble in fat solvents highly soluble in methanol and soluble to the extent of 10 to 20 units per milliliter in water It is poorly absorbed from the gastrointestinal tract High blood levels follow intravenous injection This antimycotic agent is employed for local application in the form of ointments solutions powders suppositories and gels Topical use in the treatment of *Candida* infections of the skin and vagina has been reported to be successful

The usual oral dose of nystatin is 150 mg (500 000 units) three times a day Although an occasional case of disseminated mycotic infection has been treated parenterally with nystatin with reported good results the place of this agent in the therapy of deep seated mycoses still remains to be determined

AMPHOTERICIN

Amphotericin B (Fungizone) has been administered intravenously for cryptococcosis histoplasmosis blastomycosis disseminated moniliasis and coccidioidomycosis The drug is dissolved in 5 per cent glucose to a concentration of 1 mg per 10 ml Solutions maintained at room temperature for over 24 hr must be discarded The drug solution is infused over a period of 6 hr The initial intravenous dose is 0 25 mg/kg body weight this is gradually increased to a maximum of 1 5 mg/kg If therapy is stopped and later reinstituted it is best to begin again with 0 25 mg/kg The duration of treatment varies with the nature of the infection The intramuscular dose is 20 mg dissolved in 2 ml of 5 per cent glucose combined with a local anesthetic given daily In mycotic meningitis the intrathecal injection of 0 5 to 1 mg of the drug dissolved in 5 ml of water every 48 hr has been recommended Increase in NPN chills and fever are the untoward reactions to amphotericin B If the NPN rises above 40 mg per 100 ml therapy should be stopped

NITROFURANTOIN (Furadantin)

Nitrofurantoin [N (5 nitro 2 furfurylidene) 1 aminohydantoin] is an antibacterial agent of value primarily in the treatment of some types of urinary tract infection It is poorly soluble in water The drug is bacteriostatic in high concentrations it is bactericidal Nitrofurantoin is most active against *Escherichia coli* (bactericidal) of intermediate effectiveness against *Aerobacter aerogenes* and completely without effect against *Ps aeruginosa* (*Ps pyocyanea*) The activity of the drug against *Proteus* is variable although many strains are quite sensitive *S aureus* and enterococci are inhibited by low concentrations

Nitrofurantoin is administered orally usually in a dose of 7 to 10 mg per kg (100 to 200 mg four times a day) Useful blood levels cannot be produced The drug is excreted in the urine Within 4 to 6 hr after a maximal clinical dose the concentration in the urine is 25 to 50 mg per 100 ml 8 hr after a dose the levels are low The estimated degree of antibacterial effect in the urine may at times exceed the apparent in vitro solubility at a given pH as predicted from solubility curves in the same medium With highly alkaline urine as is the case in *Proteus* infection the inhibitory effect of nitrofurantoin appears to be depressed for this reason the simultaneous administration of an acidi

individuals to prevent invasion by specific bacteria and has been most successful in protecting against infection by four agents—the beta hemolytic streptococcus the gonococcus the meningococcus and the dysentery bacilli

The administration of penicillin to individuals exposed to invasion by the beta hemolytic streptococcus affords predictable and high order of protection This antibiotic is also highly effective in the prevention of acute gonococcal urethritis A single oral dose of 250 000 units given immediately after contact has been demonstrated to reduce markedly the incidence of this disease Sulfonamides are the most effective agents for the prevention of bacillary dysentery In outbreaks due to sulfonamide insensitive organisms Chloromycetin or the tetracycline compounds may be of value The prevention of all degrees of spread of meningococcal infection is a relatively simple matter because the meningococcus is highly sensitive to sulfadiazine

Chemoprophylaxis in Acutely Ill Individuals The antimicrobial agents have been used extensively for the prevention of bacterial invasion in individuals taken suddenly ill with disorders in which these drugs have no therapeutic effect The primary diseases in which such chemoprophylaxis has been employed are of two types (1) those due to viruses and (2) those which are noninfectious in origin

One of the most common prophylactic uses of the antibiotics is in undefined viral disease of the upper respiratory tract Attempts to prevent secondary infections following the common cold while most desirable have not proved very successful Depending on the antimicrobial agent used certain pathogenic bacteria may be prevented from producing disease in the person with a viral respiratory infection However regardless of the prophylactic program employed invasion by all organisms cannot be eliminated For this reason the etiology of the complications may be altered by chemoprophylaxis but their incidence may be very little if at all changed There is considerable question whether prophylaxis should be used in primary atypical pneumonia or some of the other undefined viral pneumonias since secondary bacterial infection in untreated cases is uncommon In viral influenza the risk of superimposed bacterial disease is greater than in the undefined viral pneumonias and chemoprophylaxis may therefore have more justification

Antibiotics have often been administered in the so-called childhood diseases" to prevent secondary bacterial infection Both penicillin and Aureomycin have been reported to reduce remarkably the number of complications in measles Study of this disease has not however indicated any benefit from the administration of chemotherapeutic agents during the preeruptive or eruptive phase In fact the data have suggested that the incidence of secondary bacterial infections may be higher in patients given an antibiotic than in those not treated Failure of antimicrobial agents to protect against bacterial invasion in "respiratory" poliomyelitis has also been observed Experience in the prevention of superimposed bacterial disease in pertussis has been very disappointing with the use of Terramycin Aureomycin and Chloromycetin

It is common practice in many hospitals to administer antibiotic agents to patients with heart failure coma due to various causes cerebrovascular accidents or shock for the purpose of preventing bacterial infections Despite the wide use of such prophylaxis and the general impression that it is effective no conclusive evidence has been obtained to substantiate its usefulness Since individuals with these conditions are quite susceptible to bacterial invasion they are exposed to the risk of superinfection even if they receive antibiotics

The necessity to catheterize the urinary bladder usually arises as an acute situation Although single catheterizations are attended by a degree of risk of infection of the lower urinary tract the presence of an indwelling tube is almost certain to result in bacterial invasion of the bladder or kidneys or both The sulfonamides usually in a dose of 2 Gm a day have been used for a long time for prophylaxis in this situation The results with these drugs have been variable but in general not very beneficial The use of other antibiotic agents has not significantly altered the situation Two other approaches to this problem have been employed The first is tidal drainage this definitely reduces the risk of infection The other involves increasing the dose of the prophylactic agent to full therapeutic levels for at least 1 week after removal of the catheter because the quantities of drug used for prophylaxis frequently do not prevent bacteria from being present in appreciable numbers despite absence of active infection With cessation of treatment the organisms often multiply and invade the tissues The administration of large doses of a chemotherapeutic agent may eliminate the bacteria before they produce disease

Chemoprophylaxis in Chronic Disease While not all individuals who have had rheumatic fever have residual valvular defects their susceptibility to new episodes of the acute rheumatic state and the risk of cardiac damage make it imperative that everyone who has recovered from this disease be protected against infection by the beta hemolytic streptococcus which is responsible in most instances for recurrences The two agents which have been used most extensively for the prevention of rheumatic fever are sulfadiazine and penicillin (p 863)

It has been estimated that about 25 per cent of cases of subacute bacterial endocarditis follow den

blood brain barrier readily and in cases of meningeal inflammation the quantities in the spinal fluid may be larger than those in the plasma making it extremely valuable in tuberculous meningitis

Cultures of tubercle bacilli acquire resistance to isonicotinic acid hydrazide readily Insensitive strains are recovered from the majority of tuberculous patients who receive this drug alone for from 1 to 2 months There is no cross resistance between isonicotinic acid hydrazide and streptomycin or PAS

Isonicotinic acid hydrazide should be given in combination with streptomycin or PAS Such therapy takes advantage of the additive tuberculostatic effect and also delays considerably the speed of emergence of resistance of the organisms to either agent

Although isonicotinic acid hydrazide is relatively nontoxic a number of untoward effects have been noted following its administration They include drowsiness hyperreflexia tremor of the limbs twitching of the legs difficulty in initiation of micturition nausea abdominal discomfort transient flushing of the face pruritic skin eruptions peripheral neuropathy acute pellagra toxic hepatitis with jaundice temporary arterial vasospasm and mild psychotic reactions

Pyrazinamide and Cycloserine Two of the more recently developed antituberculous agents are cycloserine a fermentation product of *Streptomyces orchidaceus* and pyrazinamide (Aldinamide) a synthetic compound Both have been used in the treatment of human tuberculosis especially that due to organisms resistant to streptomycin or isonicotinic acid or both with promising results Considerably more study is required however before the exact place of these drugs in the therapy of tuberculosis is clearly defined their effectiveness when given in combination with other tuberculostatic agents is under investigation The usual dose of cycloserine is 0 25 Gm given four times daily while that of pyrazinamide is 0 05 Gm/kg/day Although of low toxicity cycloserine has been thought to cause epileptiform seizures changes in personality or definite depression in some patients The most serious untoward reaction to pyrazinamide is acute hepatitis joint pains nervousness palpitation feeling of tightness in the chest febrile reactions and eosinophilia have also been noted

SELECTION OF A CHEMOTHERAPEUTIC AGENT

In the therapy of infections the physician has to choose among an ever increasing number of antibacterial drugs In order to obtain the best results it is essential that he have a working knowledge of the common pathogenic microorganisms While cultural studies are perhaps theoretically desirable in every case they are not always practicable In many instances the etiology can be inferred from the onset and the clinical features of the disease Nevertheless it must be stressed that there are situations in which careful bacteriologic studies are essential to proper treatment and the conscientious physician must take whatever steps are required to obtain experienced bacteriologic help

Even when the etiology of an infectious process is determined selection of an appropriate drug does not follow automatically because there may be wide variations in susceptibility among organisms of the same or related species For example in treating a series of *Proteus* infections it will be found that some strains respond only to streptomycin others to sulfonamides Aureomycin Chloromycetin or even neomycin The cost of the different drugs has to be considered at times since there are very wide differences The nature of the illness may also affect the choice of agent for example an orally administered drug may be unsatisfactory in a patient who is vomiting In critically ill patients is is sometimes wisest to give a combination of drugs until cultural and sensitivity studies reveal which is specifically indicated In such cases cultures should always be taken *before initiation of therapy* If an individual has previously shown hypersensitivity or any other serious reaction to a drug or if he develops such untoward effects during therapy a different agent should be used if possible The approximate order of preference of various antibacterial drugs will not be tabulated as is the usual custom in this chapter Instead the reader is referred to the discussions of the therapy of *specific infections in other parts of this book* where the agents of primary and secondary value in treatment are indicated

THE PROPHYLAXIS OF INFECTION

The chemotherapeutic agents now available offer an excellent means of prophylaxis in many of the infectious diseases Chemoprophylaxis has been used primarily for four purposes (1) to protect healthy individuals either singly or in groups against invasion by specific microorganisms (2) to prevent *secondary bacterial infection in people* acutely ill with diseases for which the antimicrobial agents are not effective (3) to reduce the risk of infection in patients with various types of chronic illness and (4) to inhibit the spread of disease from areas of localized infection or to prevent infection in general in persons who have been subjected to accidental or surgical trauma

Chemoprophylaxis in Healthy Individuals Chemoprophylaxis is most commonly employed in healthy

number of people treated so that even with a con stant incidence the total number of reactions has risen and (3) repeated administration of single or multiple agents so that increasing numbers of people are conditioned to show various manifestations of hypersensitivity when exposed to these drugs

The list of the undesirable effects actually ob served and attributed to therapy with the widely used antimicrobial agents is long and varied and involves most of the organ sy tems Not all the complications have been observed with each of the chemotherapeutic substances and some have been noted with only one of them For purposes of con venience these reactions are discu sed here in rela tion to organ systems In order to conserve space they are presented in tabular form (Table 92)

Table 92 COMPLICATIONS OF CHEMOTHERAPY

I Cutaneous manifestations
  Mostly due to hypersensitivity Occur with all drugs 2 5 to 5 per cent with penicillin Most with procaine salt Lowest (less than 1 per cent) with oral rout
  1 Morbilliform rashes—commonest
  2 Scarlatiniform urticarial vesicular or bullous eruptions
  3 Purpura with or without thrombopenia
  4 Erythema multiforme
  5 Erythema nodosum
  6 Exfoliative dermatitis
  7 Inflammatory reactions at sites of infection
II Oral lesions
  Thirty three different ones de ribed Noted with all antibioti s Commonest with broad spectrum drugs
  1 Dryness burning soreness and itching of mouth and tongue
  2 Ve icular stomatitis
  3 Acute glossitis
  4 Angular stomatitis (cheilosis)
  5 Black or brown tongue
III Other manifestations of hypersensitivity
  1 Fever
  2 Contact dermatitis in nurses and pharmacists handling antibiotics
  3 Angioneuroti edema
  4 Serum sickness reaction id ntical with that fol lowing injection of heterologous serum
  5 Arthus reaction
  6 Acute anaphylactic shock (rare but commonest with penicillin)
  7 ?Polyarteritis nodosa
  8 ?Disseminated lupus erythematosus
IV Gastrointestinal and hepatic complications
  Commonest with broad-spectrum antibiotics
  1 Nausea
  2 Vomiting
  3 Diarrhea due to irritation or transformation of bowel flora

Table 92 COMPLICATIONS OF CHEMOTHERAPY (*Continued*)

  4 *Staphylococcus aureus* enteritis
  5 Membranous colitis
  6 Stomatitis and pharyngitis due to *Candida*
  7 *Jaundice and hepatitis* (*sulfanilamide*)
  8 Liver damage (Aureomycin *intravenously in* quantities larger than 2 Gm per day)
  9 Proctitis
  10 Pruritus ani
  11 Steatorrhea
V Urinary tract complication
  1 Hematuria and crystalluria (sulfonamides)
  2 Lower nephron nephro is (sulfonamides)
  3 Obstruction to urine flow (sulfonami les)
  4 Albuminuria and cylindruria (streptomycin in a id urin)
  5 Nephrotoxicity with renal failure (bacitracin polymyxin and n omycin)
VI Nervous system complications
  1 *Injury* to peripheral nerves by direct injection of antibiotic solution
  2 Peripheral neuritis (broad-sp ctrum antibiotics)
  3 Paresthe ias (streptomycin polymyxin)
  4 Damage to eighth nerve (streptomycin dihydro-streptomycin neomycin)
  5 Encephalitis (some sulfonamides)
  6 Encephalopathy due to *excessive* intrathecal doses of penicillin or streptomycin
VII Complications in blood and blood forming organs
  1 Acute hemolytic anemia (sulfonamides)
  2 Eo inophilia
  3 Thrombopenia (streptomycin Chloromycetin)
  4 Granulopenia and aplastic anemia (rare Chloro-mycetin and streptomycin)
VIII Mi cellaneous complications
  1 Negative nitrogen balance (Aureomycin)
  2 Increased riboflavin excretion (Aureomycin)
  3 Electrolyte disturbances (streptomycin)
  4 Herxheimer reaction (penicillin in syphilis)
  5 Pulmonary embolism (accidental intravenous injection of solutions in oil or of insoluble salts of antibiotics)
  6 Thrombophlebitis (intravenous injection of Au reomycin)
  7 Changes in bacterial flora of body
IX Superinfections
  These occur with all chemotherapeutic agents. They are due to invasion by normally *present or* germs or by those acquired by contact with other patients or attendants or they may result from the accidental introduction *of bacteria* during injection of drug in all instances the new *infections are* produced by strains of organisms insensitive to the antibioti being administered at the time they first appear *Infections due to Candida* (*Monilia*) may also occur during chemotherapy they *may involve* the mouth pharynx or lung or they may become generalized when they may be fatal This *type of superinfection is* being reported more frequently and is particularly important because *no specific*

tal extraction This observation and the fact that transient bacteremia occurs in from 20 to 60 per cent of persons who have teeth removed have emphasized the importance of chemoprophylaxis in patients with acquired or congenital heart disease The sulfonamides have been used for this purpose but they are not the drug of choice Penicillin is the agent employed most often and it appears to be very effective in preventing infection of the cardiac valves although bacteremia may not always be eliminated

Patients with chronic bronchitis emphysema and bronchiectasis are highly susceptible to superimposed bacterial infections It has been reported that the administration of 0 5 Gm Chloromycetin daily to individuals with these disorders resulted in a reduction in respiratory infections of 50 per cent An attempt has also been made to reduce the number of infections in diabetes mellitus by giving Aureomycin daily Fewer respiratory and urinary tract infections have been observed in treated cases these observations require confirmation

Children with cystic fibrosis of the pancreas (mucoviscidosis) are particularly susceptible to infections of the lung especially by *S aureus* For this reason Aureomycin has been used as prophylaxis in this disease Although staphylococci can often be cultured from the respiratory tract of these patients while they are receiving this drug the risk of repeated episodes of pneumonia is sharply reduced and life is prolonged and made much more comfortable

Chemoprophylaxis of Surgical or Accidental Trauma One of the most common areas of use of chemoprophylactic agents has been in elective surgery The purpose of this has been to prevent postoperative pulmonary and other infections Although the general impression has been that the administration of antimicrobial agents results in a reduction in the incidence of postoperative infectious complications careful study has emphasized the failure of prophylaxis in such cases In a number of patients subjected to elective abdominal surgery and given antibiotic agents no significant difference in the frequency of postoperative sequelae has been found when compared to a group in which no chemotherapy was used An increase in the rate of infection of clean wounds after operation despite the prophylactic use of antibiotics due primarily to invasion by penicillin resistant *S aureus* has also been noted There is no evidence that the number of postoperative pulmonary complications is decreased by chemoprophylaxis

Antibiotics in various combinations have been used extensively for preparation of the bowel for surgery The agents employed most widely for this purpose have been the so called broad spectrum antibiotics sulfonamides and neomycin Although the number of organisms in the intestine may be markedly reduced complete sterilization has rarely if ever been accomplished While it may appear that the incidence of postoperative peritonitis has been decreased by this procedure adequate controlled investigations of this problem have not been carried out Furthermore the administration of large quantities or mixtures of antibiotics is not without danger pseudomembranous colitis or acute staphylococcal enteritis (either of which may be fatal) occasionally appears during the course of antibiotic preparation of the intestine for surgery

Surgical treatment of infected areas such as the tuberculous lung localized abscesses bronchiectasis and others is an indication for the use of chemoprophylaxis prior to and after operation In this type of surgery the administration of antimicrobial agents appears justified even in the face of the risks which may be involved The type of drug employed must be determined by the location and etiology of the infection In accidental wounds or burns chemoprophylaxis has not been so successful as might have been expected Infection is not completely prevented even when combinations of antibiotics are given in these instances the organisms involved are frequently *Proteus* or *Pseudomonas* The ineffectiveness of sulfonamide powder in preventing infection in wounds is well known

In obstetrical practice patients with prolonged and difficult labor are susceptible to puerperal infection and the use of an antibiotic to prevent this complication may be justified On the other hand the general application of chemoprophylaxis to all women after completion of labor is unjustified

Dangers of Chemoprophylaxis It is important to point out that the same untoward effects which occur when antibiotic agents are used for therapeutic purposes are observed when patients who have no active infection are given these drugs The risk of the development of reactions and the difficulties which they involve must always be taken into consideration in planning a program of chemoprophylaxis When there is no evidence that chemoprophylaxis will be effective it should not be given

COMPLICATIONS OF CHEMOTHERAPY

Complications resulting from the widespread use of various chemotherapeutic agents are steadily increasing in frequency All the available drugs produce one or another type of untoward effect Some of these effects are directly toxic some are allergic and others are related to the biologic activities of the chemotherapeutic substances The reasons for the increased incidence of undesirable sequelae to chemotherapy are mainly three (1) the increase in the number of antimicrobial agents each of which may produce such reactions (2) the increase in the

days is not likely to lead to the development of a serious situation or death The combination showing the greatest additive or synergistic effect should be used

For purposes of devising the most effective antibiotic combinations the drugs have been divided into groups (1) those which are primarily bactericidal—penicillin streptomycin bacitracin and neomycin and (2) those which are primarily bacteriostatic—Aureomycin Terramycin Achromycin Chloromycetin and erythromycin If there is insufficient time for an in vitro bacteriologic study to be carried out two antibiotics in the first group may be used in combination if each alone is partially effective against the causative organism If no two drugs in this group fit this criterion and a mixture of both bactericidal and bacteriostatic agents does this combination should be given in doses that will result in full therapeutic concentrations of each antibiotic at the site of the infection

MISUSES OF CHEMOTHERAPY

There is little doubt that these drugs are often used in many situations where they are not required and that even when they are indicated failure to utilize them properly may lead to a poor clinical result Listed below are the most common misuses of the chemotherapeutic agents

1 Treatment of obscure fever
2 Choice of ineffective antibiotic
3 Inadequate or excessive doses
4 Use in insusceptible infections—measles mumps varicella poliomyelitis rheumatic fever influenza herpes simplex herpes zoster viral influenza and undefined upper respiratory tract infections
5 Improper route of administration—failure to use drug locally in pleural or joint spaces
6 Continuation of therapy with a drug to which bacterial resistance has developed
7 Failure to stop treatment in presence of a serious toxic or allergic reaction
8 Failure to alter chemotherapy when superimposed infections with insensitive organisms occur
9 Prophylaxis of minor respiratory tract infections
10 Use of sulfonamides in prevention of wound infections
11 Use of improper combinations of chemotherapeutic agents
12 Reliance on chemotherapy or prophylaxis to the exclusion of necessary surgical intervention e g drainage of localized areas of infection

Probably the most frequent chemotherapeutic misuse arises from the treatment of fever of obscure origin The mere presence of fever in the absence of localizing signs does not necessarily indicate that the temperature elevation is due to an infectious disease (see p 72) In the absence of strong clinical evidence that a febrile episode is infectious in origin particularly when there is no detectable focus chemotherapy should be delayed until adequate clinical and laboratory studies have been carried out

Table 92 COMPLICATIONS OF CHEMOTHERAPY (*Continued*)

agent for treatment of systemic involvement is presently available

Superinfections occur in about 2 per cent of patients who receive a chemotherapeutic agent The organs involved in the secondary infection are most frequently the same as those affected in the primary disease The organisms responsible for superinfections are often difficult to treat with the presently available antibacterial drugs The factors which predispose to the development of superinfection are (1) age of three years or less (2) primary disease of the lower respiratory tract (3) infection of the middle ear and (4) the use of a drug or combination of antibiotic agents which tend to have a broad antibacterial effect the wider the antimicrobial spectrum the greater is the danger of secondary bacterial invasion Superinfections appear most frequently on the fourth or fifth day after initiation of chemotherapy and may convert a benign self limited disease into a serious prolonged or even fatal one It is essential to carry out frequent bacteriologic studies whenever possible to determine changes in bacterial flora that may subsequently be responsible for a secondary infection The administration of an antibiotic active against the predominating organism and its elimination before it is responsible for infection may prevent the appearance of a complicating disease

X Development of a resistance by some bacteria to any of the chemotherapeutic drugs

None of the available antibacterial substances is free of the potentialities of producing trouble With some like the sulfonamides the risk of development of serious reactions is great with others like penicillin it is relatively small in comparison to the beneficial effects of the agent Two types of reaction are common to all the chemotherapeutic agents (1) the development of hypersensitivity and (2) the production of superinfections by resistant organisms

The fact that harmful effects may follow the use of these drugs should not discourage the physician from applying them in situations where they are definitely indicated It should however make him hesitant to employ them in cases where indications for their use are entirely absent or at most only slightly suggestive Moreover the appearance of reactions during the course of treatment does not always make the cessation of therapy mandatory especially if the drug used happens to be the only effective one available for the purpose required The severity and type of the reactions their expected course and the possibility of influencing them by proper management must all be weighed against the importance of the infection under treatment

COMBINATIONS OF CHEMOTHERAPEUTIC AGENTS

There is some evidence to suggest that the simultaneous administration of two or more antibacterial agents may be more effective in certain infections than the same drugs used individually in equal or larger amounts This evidence has been obtained largely from test tube experiments some of it has come from animal studies little from careful clinical investigation True synergistic effects are rarely derived from combinations of various chemotherapeutic substances Increased activity is usually additive With some combinations no change in antibacterial potency occurs With others one agent may to a varying degree inactivate the effectiveness of the other

There are a few chemotherapeutic combinations of proved value in clinical medicine In the management of cases of subacute bacterial endocarditis due to strains of *Streptococcus viridans* and enterococci which are relatively unresponsive to penicillin the addition of streptomycin may be helpful in effecting clinical cure In general brucellosis responds better to combinations of drugs than to single agents (see p 904) The infectious disease in which combined chemotherapy is most effective is tuberculosis The reasons for this have been pointed out above

In some of the meningitides due to organisms other than the tubercle bacillus combined chemotherapy is also more effective than single agents For example although streptomycin alone given intrathecally and intramuscularly is quite effective in the management of many cases of *H influenzae* meningitis the simultaneous use of sulfadiazine increases the number of recoveries and decreases the incidence of bacterial resistance

There is clinical support for the use of combined therapy in some infectious diseases In other situations however combinations of antibacterial substances are used because (1) satisfactory results are not obtained with a single drug (2) multiple organisms are present and (3) the causative agents have not or cannot be isolated In general the following practices appear to be sound

1 A single antibiotic can be used effectively in most infections caused by a single organism Occasionally a single antibiotic may be used in a mixed infection in which it has been proved to be of value for example penicillin in the therapy of lung abscess

2 In certain infections the proper combination of chemotherapeutic agents should be given from the start of therapy

3 If the infection does not fall into either of these categories the in vitro effect of combinations of various antibiotics should be studied provided the patient's illness is such that a delay of 2 or 3

used but has been largely abandoned because sulfonamides and antibiotics are effective against pneumococci of all types

Epidemiology Pneumococci are normal inhabitants of the upper respiratory tract in 5 to 60 per cent of the population depending upon the season Pneumococcal infection occurs predominantly during the winter months the ratio of infection in males and females is 3 2 and morbidity and mortality are higher for Negroes than whites Person to-person transmission by droplets is undoubtedly common but true epidemics of pneumococcal pneumonia are rare even in closed populations Patients with pneumococcal infection can be managed without isolation precautions

Pathogenesis The mechanism by which pneumococci damage tissue is obscure It is conceivable that toxic substances may be elaborated when they multiply in the body but no such toxin has been demonstrated It has been suggested that rapid growth of pneumococci interferes with essential metabolic processes in the host but this is supported by no firm evidence The capsular substance is known to be a necessary factor in virulence and it also protects the organism to a certain extent from engulfment by phagocytes

Invasion of the tissues of the nasopharynx rarely if ever occurs and "pneumococcal pharyngitis" is always a questionable diagnosis The organisms multiply readily and produce acute inflammation in the lung serous cavities and the endocardium The factors that ordinarily protect the lung from pneumococci include the mucus of the respiratory epithelium the direction and velocity of air currents and ciliary action Under circumstances which impair the effectiveness of these barriers pneumococci are carried to the alveoli in droplets of saliva or mucus and infection occurs pneumonia usually begins in the right lower right middle or left lower lobe Susceptibility to pneumococcal pneumonia seems to be related to common respiratory disease fatigue chilling and depression of the cough reflex Intoxication with alcohol is a well known predisposing factor and the infection is likely to be severe in alcoholics Patients with multiple myeloma are peculiarly susceptible to pneumococcal infection especially pneumonia and pneumococcal peritonitis is a frequent complication of the nephrotic syndrome in children In some parts of the world the pneumococcus is said to be a common cause of secondary infection in patients with brucellosis or trypanosomiasis Experimentally the production of pulmonary edema increases the susceptibility of animals to pneumococcal pneumonia and the frequency and severity of pneumonia in patients with chronic heart disease suggests that a similar situation also holds for man

In the pulmonary alveoli the organisms cause an outpouring of polymorphonuclear leukocytes and edema fluid The studies of Wood have shown that this fluid, which contains myriads of pneumococci spreads rapidly through bronchioles bronchi and the alveolar pores of Cohn As the infection develops neutrophils and macrophages begin to ingest pneumococci and the alveoli are filled with a fibrinous exudate containing many white cells but fewer and fewer organisms The peripheral zone of spreading edema can advance to involve additional lung tissue at a time when the older part of the lesion is actually undergoing resolution The outcome of the infection depends upon the rate at which bacteria in the edema fluid can multiply and spread into new areas as compared with the host s ability to immobilize and destroy them by phagocytosis

Bacteremia the result of entry into the blood by way of lymphatic vessels is common during the stage of spreading pulmonary infection indeed transient bacteremia probably occurs at the onset of nearly every pneumococcal infection in the lung Continued bacteremia is a poor prognostic sign not only because of the danger of metastatic infection but because it indicates poor localization of the pneumonic process

The resistance of the host to pneumococcal infection is greatly enhanced by specific antibody which not only enhances phagocytosis by "opsonizing" the organisms but as Rich has shown also retards the spread of bacteria in the tissues Recovery is not entirely dependent upon the immune response since antibody is not invariably demonstrable in patients who recover with or without chemotherapy However the dramatic recovery by crisis that used to occur before specific treatment became available usually coincided with the appearance of antibody in the blood With arrest of the infection the alveolar exudate undergoes liquefaction and the process resolves apparently by lymphatic removal of the inflammatory debris Pneumococcal pneumonia rarely produces necrosis of alveolar walls or bronchi and the lung is often restored to normal within a few days

In addition to producing pneumonia the pneumococcus can extend from the nasopharynx to produce otitis or mastoiditis paranasal sinusitis or meningitis from the lung it can extend to infect pleura pericardium or mediastinum and bacteremia may give rise to meningitis peritonitis arthritis endocarditis or other metastatic infections

PNEUMOCOCCAL PNEUMONIA

Pneumococcal pneumonia is a disease remarkable for its uniformity in contrast to other infections such as typhoid fever and tuberculosis The diseases

Section 2 Infections Due to Gram-positive Cocci

111 PNEUMOCOCCAL INFECTIONS

Ivan L Bennett Jr

Etiology The pneumococcus is a gram positive encapsulated coccus that usually grows in pairs or short chains In the diplococcal form the adjacent margins are rounded and the opposite ends slightly pointed giving the organisms a lancet shape In stained preparations of exudate gram negative forms are often present Because pneumococci produce greenish discoloration of blood agar they are sometimes confused with alpha hemolytic streptococci The two organisms can be distinguished by the bile solubility and mouse virulence of the pneumococcus or by serologic typing A simpler method utilizing inhibition of pneumococci by Optochin impregnated paper disks is accurate and less cumbersome for routine use

The capsular substances are complex polysaccharides and are the basis for dividing pneumococci into serotypes Organisms exposed to type specific antiserum show capsular swelling the *Neufeld quellung reaction* by this means about seventy five serotypes have been identified All are pathogenic for man but types 1 2 3 5 7 and 8 are encountered most frequently in clinical practice Type 14 causes pneumonia in children but is rare in adults

Specific typing of pneumococci was of great clinical importance when therapeutic antiserum was

the gross appearance of infected fluid may not differ from that of a sterile pleural effusion later however there is profuse outpouring of polymorphonuclear leukocytes and fibrin resulting in an exudate of thick greenish pus containing large plaques of fibrin The quantity of exudate may become large enough to compress the lung and displace mediastinal structures In neglected cases this leads to extensive pleural scarring with limitation of chest movement Rupture and drainage through the chest wall (*empyema necessitatis*) can occur Metastatic *brain abscess* is an occasional complication of chronic pleural empyema the origin of this appears to be septic thrombi passing through the intercostal and vertebral veins

Pericarditis A particularly serious complication is spread of infection to the pericardial sac This may be manifested by pain in the precordial region and a friction rub synchronous with the heart beat although neither of these is always present The possibility of coexisting purulent pericarditis should be considered whenever there is pleural empyema especially when the patient appears gravely ill

Metastatic Infections *Arthritis* occurs more often in infants than in adults The affected joint is swollen red and painful with a purulent effusion It subsides promptly with systemic administration of penicillin

Acute bacterial endocarditis complicates pneumococcal pneumonia in less than 0 5 per cent of cases Its manifestations and treatment will be discussed later in this section

Meningitis another complication of pneumococcal pneumonia will also be discussed subsequently

Paralytic Ileus As already noted gaseous abdominal distention is commonly present In severely ill patients this may assume serious proportions such that the term *paralytic ileus* is justified The mechanism responsible for this disturbance cannot be exactly defined It may be related in part to acute infection plus hypoxia an additional factor may be poor diffusion of swallowed nitrogen because of the lowered oxygen content of arterial blood This complication further impairs respiratory movement and constitutes a difficult problem in management

Impaired Liver Function Alterations in liver function are very common during the course of pneumococcal pneumonia and jaundice is not at all rare The mechanism of the jaundice cannot be precisely defined

Laboratory Findings X *ray* of the chest reveals a homogeneous density in the affected area of lung In well-established cases the density may occupy one or more entire lobes whereas in early cases only a portion of one lung may be involved The white blood count usually shows a polymorphonuclear *leukocytosis* ranging from 12 000 to 25 000 per cubic millimeter Normal leukocyte count or leukopenia is sometimes observed in old people or in those with overwhelming infection and bacteremia The *blood culture* is positive for pneumococci during the first 3 or 4 days of illness in 20 to 25 per cent of cases The *sputum* when stained by Gram s method shows polymorphonuclear leukocytes and moderate numbers of gram positive cocci singly and in pairs These can be typed directly by the Neufeld capsular swelling technique but this procedure is not essential for present methods of therapy

DIFFERENTIAL DIAGNOSIS OF PNEUMONIA

Fever cough and pulmonary consolidation on physical or x ray examination form a symptom complex that can be produced by many diseases of infectious toxic or other etiology

Staphylococcal pneumonia (p 842) is likely to be encountered in children in adults during or after an epidemic of influenza and in debilitated elderly individual as a nosocomial infection The clinical picture is less uniform than that of pneumococcal pneumonia varying from bronchitis with few systemic symptoms to a fulminating infection Multiple chills hectic fever early formation of lung abscesses empyema and in infants pyopneumothorax suggest the diagnosis The sputum is often grossly bloody or purulent culture of sputum and blood establishes the diagnosis Positive blood cultures should alert the clinician to the possibility that pulmonary involvement is secondary to a focus of staphylococcal infection elsewhere in the body

Hemolytic streptococcal pneumonia (p 853) can also occur in association with influenza The clinical picture closely resembles that of pneumococcal pneumonia but multiple chills hectic fever early prostration and rapid pleural involvement with accumulation of fluid or associated streptococcal pharyngitis are often helpful signs Diagnosis can be made by blood and sputum culture or by finding a rise in antistreptolysin 0 titer in convalescent serum

Friedlander bacillus pneumonia (p 883) is commonest in males past middle age especially in alcoholics The patient is usually severely ill the sputum tends to be thick and tenacious physical findings in the chest are often surprisingly scanty despite massive consolidation by x ray nausea diarrhea jaundice and delirium are more frequent than in pneumococcal infections and large numbers of gram negative bacilli are usually present in stained smears of sputum

Tularemia (p 905) of the ulceroglandular or typhoidal type is often accompanied by pulmonary lesions There may be no respiratory symptoms and a paucity of physical signs or pleurisy hemoptysis

produced by different pneumococcal serotypes show little variation in severity or in clinical manifestations. The prognosis in type 3 pneumococcal pneumonia is usually regarded as poor; this is in large measure attributable to the frequency with which type 3 infections occur in patients with other debilitating diseases such as diabetes or congestive heart failure. However, the type 3 pneumococcus possesses an unusually thick capsule, is especially difficult for neutrophils to engulf, and is the pneumococcus most likely to produce abscess formation in the lungs of man and experimental animals; these facts suggest that its virulence is partly intrinsic and not wholly the result of its attacking susceptible hosts. It is still customary to classify pneumococcal pneumonias as *lobar*, a process involving one or more large segments or lobes of the lung, or *bronchopneumonia*, in which there is patchy involvement, usually of both lungs. This distinction now has little clinical importance; treatment is the same for both anatomic types when the etiologic organism is the same, and prognosis depends upon other factors. The usual lesion in adults is lobar in distribution, but in children and the aged bronchopneumonias are frequent.

Manifestations Pneumonia is frequently preceded for a few days by coryza or some other form of common respiratory disease. The onset is usually so abrupt that patients can often state the exact hour that illness began. There is a sudden *shaking chill* in more than 80 per cent of the cases, rapid rise in temperature, and corresponding tachycardia. It is unusual for patients with pneumococcal pneumonia to experience more than a single rigor unless antipyretic drugs are administered, and repeated chills should suggest another etiologic agent.

About 75 per cent of patients develop severe *pleuritic pain* and *cough* productive of pinkish or "rusty" mucoid sputum within a few hours. The chest pain is agonizing, and respirations become rapid, shallow, and grunting as the patient tries to splint the affected side. Many patients are mildly cyanotic and show dilatation of the alae nasae when first seen. Patients appear acutely ill, but nausea, headache, malaise, and other complaints are unusual, and most individuals are alert and far from prostrated; the pleuritic pain is the dominant complaint.

Physical examination reveals restricted motion of the affected hemithorax, impaired or flat percussion note with increased fremitus over the involved area, and, usually, decreased breath sounds. Later bronchial breathing, pectoriloquy, and fine moist rales are evident.

In the untreated disease there is sustained fever of 102.5 to 105 F, continued pleuritic pain, cough and sputum, and gaseous distention is frequent. Herpes labiales is a common complication. After 7 to 10 days there is diaphoresis, abrupt defervescence, and dramatic improvement in manifestations: the crisis.

In cases which terminate fatally there is usually extensive *pulmonary involvement, and dyspnea*, cyanosis, and tachycardia are prominent. Circulatory collapse or a picture resembling forward heart failure is common. Death in a few patients is associated with empyema or some other suppurative complication.

Effect of Specific Chemotherapy Pneumococcal pneumonia usually terminates promptly when an appropriate antimicrobial drug is given. Within 12 to 36 hr after initiation of treatment with penicillin, temperature, pulse, and respiration fall to normal, pleuritic pain subsides, and the spread of the inflammatory process is halted.

Complications The typical course of pneumococcal pneumonia just described can be modified by the development of one or more local or distant complications.

In the Lung *Atelectasis* of all or part of a lobe may occur during the active stage of pneumonia or after treatment has been instituted. The patient may complain of sudden recurrence of pleuritic pain and show rapid respirations. Small areas of atelectasis are sometimes detected by x-ray in the absence of symptoms. These areas usually clear with coughing and deep breathing, but bronchoscopic aspiration is occasionally necessary. If atelectasis is allowed to persist, the affected area becomes fibrotic and functionless. *Delayed resolution* The removal of exudate from the lung following pneumococcal infection is usually complete within a few days, but occasionally, especially in elderly individuals, consolidation persists for longer periods. Sometimes the involved area never becomes reaerated and fibrosis results. *Lung abscess* is a rare sequel to pneumococcal infection. It is manifested clinically by continued fever and profuse expectoration of purulent sputum. X-ray shows one or more cavities. This complication is exceedingly rare in patients who receive penicillin therapy and is more likely to result from type 3 infections.

In Adjacent Structures *Pleural effusion* is noted in about 5 per cent of patients with pneumococcal pneumonia, even with specific therapy. The amount of fluid is usually not sufficient to cause obvious displacement of mediastinal structures. If it does not become infected, it is spontaneously reabsorbed within a week or two.

Prior to the introduction of effective chemotherapy, pneumococcal infection of the pleura with *empyema* occurred in 5 to 8 per cent of patients with pneumococcal pneumonia; it is now observed in less than 1 per cent of treated cases. It is manifested by persistent fever or pleuritic pain, together with signs of pleural effusion. In the early stages

hilar nodes and foreign body are important causes of persistent collapse although plugging of bronchi by inspissated mucus is by far the most frequent cause

Pulmonary adenomatosis (p 1399) a diffuse neoplastic disease can be accompanied by fever profuse glairy sputum and hemoptysis with various x ray findings *and is sometimes mistaken at first* for acute bacterial pneumonia or tuberculosis

Pulmonary infarction is especially frequent in patients with congestive heart failure and after surgical procedures Prostatic surgery and parturition are particularly likely to lead to embolization from the pelvic veins Pulmonary embolization may be asymptomatic but in many patients there are sudden pleuritic pain dyspnea anxiety transient hypotension and hemoptysis Fever is common but true chills are rare Icterus may accompany pulmonary infarcts in individuals with congestive heart failure Signs of consolidation and pleural fluid are common and *often evidence of phlebo* thrombosis can be detected in the legs

Septic pulmonary infarcts with abscess formation and cavitation should always suggest puerperal sepsis or infected abortions with pelvic thrombophlebitis in a female For reasons that are obscure phlebothrombosis and pulmonary infarction are relatively frequent complications of convalescence from psittacosis

The lungs of patients with *uremia* sometimes show x ray changes consisting of infiltrations that flare toward the periphery from both hilar areas Roentgenographically the changes in the lungs of patients with *acute pulmonary edema* and *heart failure* are sometimes surprisingly well localized to a segment or lobe of one lung

The inhalation of *noxious materials or irritants* (p 1402) including smoke chlorine phosgene cadmium fumes bagasse fibers and other organic dusts can lead to bronchitis bronchiolitis and patchy or even lobar infiltration in the lung, dyspnea and low grade fever The diagnosis is usually made by eliciting a *history of exposure* The ingestion of gasoline or kerosene (p 775) is almost invariably complicated by severe chemical bronchopneumonia

Pneumonitis is detectable by physical examination or x ray in some patients with erythema multiforme (p 1710) lupus erythematosus (p 1700) rheumatic fever (p 861) or intestinal helminthiasis (pp 1120 and 1123) Infectious mononucleosis (p 1151) and lymphocytic choriomeningitis (p 1064) are sometimes accompanied by pulmonary infiltrations and occasionally by signs of respiratory irritation with cough and sputum Pulmonary lesions usually in the form of scattered nodular densities with accompanying cough dyspnea and cyanosis occur in a small proportion of patients with smallpox (p 1060) chickenpox (p 1058) or measles (p 1056) the involvement in these diseases is believed to be caused by the virus rather than by secondary bacterial invaders Rupture of amebic abscess into the pleural cavity can be mistaken for acute pneumonia (p 1110) and in a few patients with estivoautumnal malaria blockage of pulmonary capillaries by parasites can lead to confusion with respiratory infections of various types (p 1112)

PNEUMOCOCCAL MENINGITIS

The pneumococcus is second only to the meningococcus as a cause of purulent meningitis in adults in children influenzal meningitis is also more frequent than pneumococcal infection

Pneumococcal meningitis can develop as a "primary" disease without preceding signs of infection elsewhere as a complication of pneumococcal pneumonia by extension from otitis mastoiditis or sinusitis or following a skull fracture which creates an opening into the nasal cavity or paranasal sinuses Patients with pneumococcal endocarditis frequently develop meningeal infection Patients with multiple myeloma seem to be prone to pneumococcal infection of the meninges just as they are to pneumonia

The *manifestations* are those of any acute pyogenic meningitis and include chills fever headache nuchal rigidity Kernig and Brudzinski signs delirium and cranial nerve palsies Evidence of otitis sinusitis or pneumonia should be carefully sought by physical and roentgenographic examination in all patients

The *spinal fluid* is under increased pressure appears cloudy often with a greenish tint and shows a high protein and low glucose content Stained smears usually reveal myriads of gram positive diplococci and polymorphonuclear leukocytes in some patients the number of cells in the spinal fluid is surprisingly small much of the cloudiness being produced by the bacterial content

With appropriate chemotherapy recovery can be expected in 70 to 85 per cent of cases Before penicillin was available the mortality rate exceeded 95 per cent, and sulfonamides did little to reduce this Relapse can occur but is unusual if adequate treatment is carried out Subarachnoid block the result of accumulation of large amounts of thick exudate in the meningeal space and at the base of the brain is now an unusual complication.

PNEUMOCOCCAL ENDOCARDITIS

Endocarditis is almost always a complication of pneumonia The clinical picture is that of acute bacterial endocarditis (p 973) with remittent fever petechial hemorrhages splenomegaly and

and consolidation may dominate the clinical picture Patients are usually very ill with fevers of 104 to 106 F and the disease does not respond to penicillin Agglutinins for the organism may not appear until the third week A history of contact with wild rabbits or the finding of a cutaneous ulcer and regional lymphadenitis is helpful in diagnosis

Infection by other bacteria can produce pneumonia Pulmonary involvement is frequent in patients with *Salmonella* bacteremia especially in *Salmonella suipestifer* infections (p 890) *Hemophilus influenzae* is a common cause of lung disease in children in adults it occasionally produces a necrotizing bronchiolitis and in elderly patients with chronic lung disease it may produce bronchopneumonia (p 896) The diagnosis is usually made only by culture of sputum Pulmonary lesions with cough and hemoptysis can be prominent in Weil s disease (p 1014) and of course the plague bacillus can cause an overwhelming and rapidly fatal pneumonia especially when plague becomes epidemic (p 909) sporadic infection by *Pasteurella pestis* is more likely to be the bubonic form

Primary atypical pneumonia (p 1044) is usually more insidious in onset than bacterial pneumonias chills are infrequent fever is usually lower pleuritic pain and effusions are unusual headache and malaise are prominent the cough is hacking irritating and productive of small amounts of mucoid sputum rarely blood tinged and physical signs are scanty in comparison with x ray changes Herpes labialis is unusual The leukocyte count is usually normal although it may be increased during the second week of illness and in 30 to 50 per cent of cases cold agglutinins are demonstrable during the second week

Psittacosis (p 1052) is often described as a severe form of atypical pneumonia Actually most patients with this disease are febrile and have systemic symptoms of headache lethargy and malaise for several days before pulmonary lesions develop The pulse is usually slow in proportion to fever and patients are sometimes suspected of having typhoid A history of contact with parrots poultry or other birds may be helpful The leukocyte count is normal and diagnosis is established by finding complement fixing antibodies in rising titer Splenomegaly is present in a variable proportion of patients with psittacosis and is sometimes a clue to diagnosis

Q fever (p 1037) is characterized by severe headache sustained fever and usually minimal symptoms of respiratory disease although a large proportion of patients show roentgenographic evidence of patchy pulmonary involvement A history of contact with cattle suggests the possibility of Q fever which is widely distributed in this country

Acute tuberculous pneumonia (p 939) may be difficult to recognize because in the early stages tubercle bacilli may not be demonstrable in the sputum the early consolidation is often the result of an inflammatory response to discharge of tuberculin containing material into the lung Fever is usually remittent or intermittent and may not exceed 102 F Many patients with tuberculous pneumonia feel surprisingly well despite consolidation of an entire lobe *Pleurisy with effusion* is seldom abrupt in onset its course is prolonged and physical and x ray findings are those of accumulating pleural fluid rather than parenchymal consolidation The leukocyte count is usually normal Herpes labialis is rare in tuberculosis

Blastomycosis (p 987) can produce acute lobar or bronchopneumonia with high fever pleuritic pain dyspnea and pleural fluid The organisms are usually easily found in the sputum and cavitation develops early in the illness The usual course of pulmonary blastomycosis is less acute with low grade fever and slow evolution of the pulmonary findings Typical skin lesions of blastomycosis or concomitant involvement of bone are aids in diagnosis

Actinomycosis of the lung (p 984) is usually a more chronic disease than bacterial pneumonia and is more likely to be confused with tuberculosis or lung tumors The diagnosis is made by finding sulfur granules in sputum or by culturing the organism Other mycotic infections of the lung include *primary histoplasmosis* (p 991) which can produce an acute illness with fever cough and multiple nodular pulmonary densities that lasts for several weeks and *primary coccidioidomycosis* (p 988) distinguishable in endemic areas by pulmonary infiltration fever eosinophilia and often erythema nodosum

Lung abscess may have an abrupt onset with chill fever and pleuritic pain and can be confused with acute pneumonias The development of cavitation in a well circumscribed pulmonary density and profuse purulent sputum makes the diagnosis clear In individuals with chronic abscess weight loss is prominent and cavitation readily apparent There is usually intermittent or remittent fever A history of epilepsy alcoholic intoxication anesthesia dental extraction tonsillectomy or aspiration of a foreign body may be elicited Abscess may be the first sign of bronchogenic carcinoma

Atelectasis may occur in patients confined to bed especially if respiratory motion is limited (as after an abdominal operation) or when the cough reflex is depressed by drugs or central nervous system disease Infection of the collapsed pulmonary segment leads to fever pleuritic pain and purulent sputum There is often a shift of the mediastinum toward the affected side Tumor enlarged

hilar nodes and foreign body are important causes of persistent collapse although plugging of bronchi by inspissated mucus is by far the most frequent cause

Pulmonary adenomatosis (p 1399) a diffuse neoplastic disease can be accompanied by fever profuse glairy sputum and hemoptysis with various x ray findings and is sometimes mistaken at first for acute bacterial pneumonia or tuberculosis

Pulmonary infarction is especially frequent in patients with congestive heart failure and after surgical procedures Prostatic surgery and parturition are particularly likely to lead to embolization from the pelvic veins Pulmonary embolization may be asymptomatic but in many patients there are sudden pleuritic pain dyspnea anxiety transient hypotension and hemoptysis Fever is common but true chills are rare Icterus may accompany pulmonary infarcts in individuals with congestive heart failure Signs of consolidation and pleural fluid are common and often evidence of phlebothrombosis can be detected in the legs

Septic pulmonary infarcts with abscess formation and cavitation should always suggest puerperal sepsis or infected abortions with pelvic thrombophlebitis in a female For reasons that are obscure phlebothrombosis and pulmonary infarction are relatively frequent complications of convalescence from psittacosis

The lungs of patients with *uremia* sometimes show x ray changes consisting of infiltrations that flare toward the periphery from both hilar areas Roentgenographically the changes in the lungs of patients with *acute pulmonary edema* and *heart failure* are sometimes surprisingly well localized to a segment or lobe of one lung

The inhalation of *noxious materials or irritants* (p 1402) including smoke chlorine phosgene cadmium fumes bagasse fibers and other organic dusts can lead to bronchitis bronchiolitis and patchy or even lobar infiltration in the lung dyspnea and low grade fever The diagnosis is usually made by eliciting a history of exposure The ingestion of gasoline or kerosene (p 775) is almost invariably complicated by severe chemical bronchopneumonia

Pneumonitis is detectable by physical examination or x ray in some patients with erythema multiforme (p 1710) lupus erythematosus (p 1700) rheumatic fever (p 861) or intestinal helminthiasis (pp 1120 and 1123) Infectious mononucleosis (p 1151) and lymphocytic choriomeningitis (p 1064) are sometimes accompanied by pulmonary infiltrations and occasionally by signs of respiratory irritation with cough and sputum Pulmonary lesions usually in the form of scattered nodular densities with accompanying cough dyspnea and cyanosis occur in a small proportion of patients with smallpox (p 1060) chickenpox (p 1058) or measles (p 1056) the involvement in these diseases is believed to be caused by the virus rather than by secondary bacterial invaders Rupture of amebic abscess into the pleural cavity can be mistaken for acute pneumonia (p 1110) and in a few patients with estivoautumnal malaria blockage of pulmonary capillaries by parasites can lead to confusion with respiratory infections of various types (p 1112)

PNEUMOCOCCAL MENINGITIS

The pneumococcus is second only to the meningococcus as a cause of purulent meningitis in adults in children influenzal meningitis is also more frequent than pneumococcal infection

Pneumococcal meningitis can develop as a primary disease without preceding signs of infection elsewhere as a complication of pneumococcal pneumonia by extension from otitis mastoiditis or sinusitis or following a skull fracture which creates an opening into the nasal cavity or paranasal sinuses Patients with pneumococcal endocarditis frequently develop meningeal infection Patients with multiple myeloma seem to be prone to pneumococcal infection of the meninges just as they are to pneumonia

The *manifestations* are those of any acute pyogenic meningitis and include chills fever headache nuchal rigidity Kernig and Brudzinski signs delirium and cranial nerve palsies Evidence of otitis sinusitis or pneumonia should be carefully sought by physical and roentgenographic examination in all patients

The *spinal fluid* is under increased pressure appears cloudy often with a greenish tint and shows a high protein and low glucose content Stained smears usually reveal myriads of gram positive diplococci and polymorphonuclear leukocytes in some patients the number of cells in the spinal fluid is surprisingly small much of the cloudiness being produced by the bacterial content

With appropriate chemotherapy recovery can be expected in 70 to 85 per cent of cases Before penicillin was available the mortality rate exceeded 95 per cent and sulfonamides did little to reduce this Relapse can occur but is unusual if adequate treatment is carried out Subarachnoid block the result of accumulation of large amounts of thick exudate in the meningeal space and at the base of the brain is now an unusual complication

PNEUMOCOCCAL ENDOCARDITIS

Endocarditis is almost always a complication of pneumonia The clinical picture is that of acute bacterial endocarditis (p 975) with remittent fever petechial hemorrhages splenomegaly and

metastatic infection of the lungs meninges joints eye and other tissues The infection can attack normal valves and is particularly likely to occur on the aortic valve The valvular infection is destructive and loud murmurs and heart failure develop rapidly Rupture or perforation of cusps or even rupture of the aorta can occur The blood culture is consistently positive for the pneumococcus yet at the same time antibodies for the infecting organism can usually be demonstrated in the blood a combination of findings seldom observed except in endocarditis or brucellosis The rapid destruction of the valvular structures combined with a striking tendency to the development of myocardial abscess in the region of the valve ring makes pneumococcal endocarditis a difficult disease to cure despite the sensitivity of the organism to penicillin

PNEUMOCOCCAL PERITONITIS

Pneumococcal peritonitis occasionally occurs in young girls presumably the vagina and fallopian tubes are the portal of entry Symptoms are fever pain abdominal distention vomiting and accumulation of peritoneal fluid The diagnosis is made by examination of the purulent ascitic fluid blood cultures are often positive and a polymorphonuclear leukocytosis is the rule

Peritonitis is also a frequent complication of the nephrotic syndrome particularly in children in whom there may be repeated episodes of this infection

TREATMENT

Specific Chemotherapy Penicillin is the drug of choice in all pneumococcal infections The minimum curative dosage for *pneumonia* is less than 60 000 units daily and a total daily dose of 600 000 units as one injection of a depot preparation or multiple injections of aqueous crystalline penicillin provides a good margin of safety Treatment should be continued until the patient has been afebrile for 48 to 72 hr The response is usually dramatic and relapse is virtually unheard of Pneumococcal pneumonia can be treated adequately with oral penicillin in a dosage of 1 2 to 2 4 million units daily

Peritonitis usually responds within 36 to 48 hr to 600 000 units of penicillin daily

Pneumococcal *meningitis* is best treated with massive amounts of penicillin intramuscularly a minimum dosage is 12 million units of aqueous penicillin daily and in many clinics larger amounts are used and Benemid is also given to impede renal excretion of the antibiotic The intrathecal administration of penicillin in the amount of 5 000 or 10 000 units in 10 ml physiologic saline solution each day is still advocated by some but has been abandoned by most clinicians There is convincing evidence that the addition of sulfadiazine to this regimen affords no advantage and that the supplementary administration of chlortetracycline (and presumably other broad spectrum drugs) *actually* exerts a deleterious effect producing antibiotic antagonism (see p 830) In the presence of sinusitis or otitis surgical drainage should be carried out as soon as feasible The response of meningitis is usually less dramatic than that of pneumonia patients often remain febrile and disoriented and signs of meningeal irritation may persist for several days improvement becoming gradually evident with continued treatment

In *pneumococcal endocarditis* also large doses are required—6 to 12 million units daily by intramuscular injection Rapidly developing heart failure in these patients and the tendency to myocardial abscess formation however often lead to a fatal outcome despite large doses of antibiotics

Sulfonamides are effective in pneumococcal pneumonia but their action is not so prompt or dramatic as that of penicillin they are virtually useless in meningitis and endocarditis

The *tetracycline* drugs and *chloramphenicol* are effective in the treatment of pneumonia in doses of 1 0 to 2 0 Gm daily They are recommended only for patients who have exhibited an untoward reaction to penicillin

Arthritis responds to systemic penicillin aspiration and intraarticular instillation of the drug are rarely necessary *Empyema should be watched for* and treated as early as possible When an effusion is detected the fluid should be examined for organisms and if they are found 50 000 to 200 000 units of penicillin should be injected intrapleurally Daily aspiration of fluid and instillation of penicillin should be carried out until cultures are persistently negative Fluoroscopic guidance may be needed for aspiration of small empyema pockets If the exudate becomes especially thick and viscid streptokinase streptodornase (Varidase) may facilitate its withdrawal Aspiration of exudate and instillation of penicillin is treatment of choice in *pericarditis* also In empyema or pericarditis the development of loculation and thick exudate with difficulty in aspiration should lead to consideration of surgical drainage While there has been good success in the medical management of these infections of serous cavities thoracotomy will sometimes shorten a patient s hospital course and should not be neglected when difficulties develop in medical treatment

Other Measures *Oxygen* may be used for intense cyanosis in pneumonia but is likely to aggravate abdominal distention Codeine 30 to 60 mg every few hours will usually control mild *pleuritic pain* A chest binder or adhesive strapping of the affected

side may diminish pain but increases the likelihood of atelectasis and interferes with subsequent examinations When pain is severe intercostal nerve block by injection of 2 0 ml of 1 per cent procaine beneath the rib margins proximal to the site of pain is usually effective The procedure is not technically difficult or dangerous Other methods of relieving pleuritic pain are usually transient in their effect but are sometimes worth trying they include ethyl chloride spray over the painful area intravenous injection of calcium gluconate and intravenous injection of tetraethylammonium chloride

PROGNOSIS

With proper chemotherapy the mortality from pneumococcal pneumonia has fallen to less than 5 per cent and in many clinics to less than 1 per cent The recovery rate in meningitis is 70 to 85 per cent Pneumococcal endocarditis is still fatal in at least half the cases

Signs of poor prognosis in pneumonia include leukopenia circulatory collapse multilobar involvement and persistent bacteremia Jaundice is often prominent in fatal cases but icterus alone is not a poor prognostic finding

112 STAPHYLOCOCCAL INFECTIONS

David E Rogers

Staphylococci cause the majority of superficial suppurative infections in man They are also responsible for certain infections of the lungs long bones and kidneys

In recent years staphylococcal infections have assumed increasing clinical importance because of their failure to respond satisfactorily to antimicrobial drugs Certain features of staphylococcal disease have helped to create this situation These are (1) the tendency of staphylococci to invade the tissues of debilitated patients (2) the rapid tissue destruction and abscess formation which characterize infection caused by these microorganisms and (3) the capacity of staphylococci to develop resistance to antibacterial drugs

BACTERIOLOGY

Staphylococci are members of the genus *Micrococcus* which includes many saprophytic cocci that do not cause human infection The parasitic micrococci of primary concern in medicine are now grouped in the species *Micrococcus pyogenes* Through established medical usage these pathogenic micrococci are termed *staphylococci* They are normal inhabitants of the skin and anterior nares of man

Staphylococci are spherical gram positive bacteria which grow abundantly in the usual meat extract or infusion media On solid media colonies develop characteristic pigmentation by which three varieties can be differentiated *Micrococcus pyogenes* var *aureus* (*Staphylococcus aureus*) grayish yellow *Micrococcus pyogenes* var *albus* (*Staphylococcus albus*) ivory white and *Micrococcus citreus* orange yellow Most human infections are caused by *S aureus* The name staphylococcus derives from the characteristic grapelike clusters of organisms seen in stained smears prepared from colonies growing on solid media (Greek *staphule*—grape) Examination of stained smears of pus shows

metastatic infection of the lungs meninges joints eye and other tissues The infection can attack normal valves and is particularly likely to occur on the aortic valve The valvular infection is destructive and loud murmurs and heart failure develop rapidly Rupture or perforation of cusps or even rupture of the aorta can occur The blood culture is consistently positive for the pneumococcus yet at the same time antibodies for the infecting organism can usually be demonstrated in the blood a combination of findings seldom observed except in endocarditis or brucellosis The rapid destruction of the valvular structures combined with a striking tendency to the development of myocardial abscess in the region of the valve ring makes pneumococcal endocarditis a difficult disease to cure despite the sensitivity of the organism to penicillin

PNEUMOCOCCAL PERITONITIS

Pneumococcal peritonitis occasionally occurs in young girls presumably the vagina and fallopian tubes are the portal of entry Symptoms are fever pain abdominal distention vomiting and accumulation of peritoneal fluid The diagnosis is made by examination of the purulent ascitic fluid blood cultures are often positive and a polymorphonuclear leukocytosis is the rule

Peritonitis is also a frequent complication of the nephrotic syndrome particularly in children in whom there may be repeated episodes of this infection

TREATMENT

Specific Chemotherapy Penicillin is the drug of choice in all pneumococcal infections The minimum curative dosage for *pneumonia* is less than 60 000 units daily and a total daily dose of 600 000 units as one injection of a depot preparation or multiple injections of aqueous crystalline penicillin provides a good margin of safety Treatment should be continued until the patient has been afebrile for 48 to 72 hr The response is usually dramatic and relapse is virtually unheard of Pneumococcal pneumonia can be treated adequately with oral penicillin in a dosage of 1 2 to 2 4 million units daily

Peritonitis usually responds within 36 to 48 hr to 600 000 units of penicillin daily

Pneumococcal *meningitis* is best treated with massive amounts of penicillin intramuscularly a minimum dosage is 12 million units of aqueous penicillin daily and in many clinics larger amounts are used and Benemid is also given to impede renal excretion of the antibiotic The intrathecal administration of penicillin in the amount of 5 000 or *10 000 units in 10 ml physiologic saline solution* each day is still advocated by some but has been abandoned by most clinicians There is convincing evidence that the addition of sulfadiazine to this regimen affords no advantage and that the supplementary administration of chlortetracycline (and presumably other broad spectrum drugs) actually exerts a deleterious effect producing antibiotic antagonism (see p 830) In the presence of sinusitis or otitis surgical drainage should be carried out as soon as feasible The response of meningitis is usually less dramatic than that of pneumonia patients often remain febrile and disoriented and signs of meningeal irritation may persist for several days improvement becoming gradually evident with continued treatment

In *pneumococcal endocarditis* also large doses are required—6 to 12 million units daily by intramuscular injection Rapidly developing heart failure in these patients and the tendency to myocardial abscess formation however often lead to a fatal outcome despite large doses of antibiotics

Sulfonamides are effective in pneumococcal pneumonia but their action is not so prompt or dramatic as that of penicillin they are virtually useless in meningitis and endocarditis

The *tetracycline* drugs and *chloramphenicol* are effective in the treatment of pneumonia in doses of 1 0 to 2 0 Gm daily They are recommended only for patients who have exhibited an untoward reaction to penicillin

Arthritis responds to systemic penicillin aspiration and intraarticular instillation of the drug are rarely necessary *Empyema* should be watched for and treated as early as possible When an effusion is detected the fluid should be examined for organisms and if they are found 50 000 to 200 000 units of *penicillin should be injected intrapleurally* Daily aspiration of fluid and instillation of penicillin should be carried out until cultures are persistently negative Fluoroscopic guidance may be needed for aspiration of small empyema pockets If the exudate becomes especially thick and viscid streptokinase streptodornase (Varidase) may facilitate its withdrawal Aspiration of exudate and instillation of penicillin is treatment of choice in *pericarditis* also In empyema or pericarditis the development of loculation and thick exudate with difficulty in aspiration should lead to consideration of surgical drainage While there has been good success in the medical management of these infections of serous cavities thoracotomy will sometimes shorten a patient s hospital course and should not be neglected when difficulties develop in medical treatment

Other Measures *Oxygen* may be used for intense cyanosis in pneumonia but is likely to aggravate abdominal distention Codeine 30 to 60 mg every few hours will usually control mild *pleuritic pain* A chest binder or adhesive strapping of the affected

more frequent in infants than in adults Acute staphylococcal osteomyelitis is primarily a disease of children although this may be attributable solely to anatomic differences between growing and mature bones Abscess formation is less common and persistent bacteremia more frequent in infants than in adults

Nevertheless recurrent furunculosis is common at any age and conventional serologic techniques often fail to demonstrate humoral antibodies following prolonged staphylococcal infections Immunization of experimental animals with exotoxin coagulase or whole organisms will usually prolong the course of induced staphylococcal infections but does not prevent eventual death There is no firm evidence to indicate that staphylococcal infection in man can be significantly modified by vaccination or "desensitization using current techniques

Epidemiology Pathogenic staphylococci are normal residents of the anterior nares and skin of 30 to 60 per cent of human beings In certain groups notably hospital personnel and patients the carrier rate is consistently higher than in the general population Over 90 per cent of newborn infants in nurseries acquire staphylococci as a part of the flora of the nares by the age of 2 weeks

Staphylococci remain viable for long periods in dust and on blankets and clothing It is probable that organisms are frequently spread by the nasal discharges of carriers as airborne particles although active staphylococcal infections are believed by some to be a more likely source of cross infection than the simple carrier state

Antimicrobial Resistance The introduction of each drug effective against staphylococci has been followed by an increase in the number of strains specifically resistant to its action When penicillin first came into general use less than 10 per cent of staphylococci isolated from patients or carriers were resistant to penicillin in vitro By 1957 50 to 80 per cent of staphylococcal strains isolated from hospitalized patients throughout the world were insusceptible to penicillin Similar emergence of resistant staphylococci has followed the use of streptomycin the tetracyclines chloramphenicol and erythromycin The incidence of resistance to each different antibiotic correlates closely with the frequency of use of that particular drug

Most observations on the occurrence of strains resistant to antibiotics have been made in hospitals and similar institutions where antimicrobial usage is heaviest Many studies of nasal flora have shown that susceptible staphylococci carried by patients entering a hospital are likely to be replaced by drug resistant strains already present in the institutional environment these resistant strains are also acquired and carried by hospital personnel creating a permanent reservoir Staphylococci isolated from population groups outside hospitals have not shown such a striking increase in resistance This fact is of great importance in preliminary decisions regarding therapy of staphylococcal infections

SUPERFICIAL INFECTIONS

Simple infection of hair follicles manifested by a minute erythematous nodule without involvement of the surrounding skin or deeper tissues is termed *folliculitis* Chronic recurrent folliculitis of the beard area is called *sycosis barbae*

A more extensive infection of follicles or sebaceous glands which penetrates deeper tissues results in the familiar *furuncle* or *boil* Itching and mild pain in the area are soon followed by progressive local swelling and erythema The overlying skin becomes thinned tense shiny and exquisitely painful on pressure or motion Relief of pain is prompt after spontaneous or surgical drainage The acne of adolescence is often complicated by secondary furunculosis Staphylococcal infection of the apocrine sweat glands in the axillary and genital areas (*hidradenitis suppurativa*) can become deep seated and chronic prone to recurrence and scarring and extremely resistant to treatment other than total surgical excision

Staphylococcal infections in the thick fibrous inelastic skin of the neck and upper back frequently lead to the formation of a *carbuncle* The relative thickness and impermeability of the overlying skin leads to lateral extension and loculation of the suppurative process and a large indurated extremely painful lesion results Carbuncles are generally accompanied by rigors fever leukocytosis and prostration Bacteremia is common

OSTEOMYELITIS

Staphylococci are responsible for the majority of cases of *acute osteomyelitis* This infection occurs almost exclusively in children under the age of twelve and is slightly commoner in males Bone involvement follows the hematogenous dissemination of bacteria At least 50 per cent of patients give a history of a recent furuncle or other superficial staphylococcal infection The frequent localization of the disease in the diaphyseal end of long bones is thought to be a result of the endarterial circulation to the diaphysis Approximately 25 per cent of patients also give a history of trauma to the involved area

Once established the infection spreads through the growing juxtaepiphyseal bone to the periosteum or along the marrow cavity If the process reaches the subperiosteal space the periosteum is lifted a subperiosteal abscess forms and rupture with infection of the subcutaneous tissues can occur

the bacteria in small clusters diploids or short chains In such preparations staphylococci retain their uniform roundness in contrast to the elongated forms assumed by pneumococci Staphylococci can often be seen within the cytoplasm of polymorphonuclear leukocytes in pus an uncommon finding in other gram positive coccal infections

Several laboratory methods can be used to recognize pathogenic staphylococci Most strains isolated from active infections lyse rabbit human and sheep erythrocytes ferment mannite and hydrolyze phenolpthalein phosphate A majority of pathogenic strains produce coagulase a substance which reacts with a factor in serum to produce a thrombin like product that clots human plasma This serum cofactor is lacking in many lower animals Other toxic products of staphylococci are mentioned below

Different strains of pathogenic staphylococci can be recognized by specific patterns of lysis by bacteriophages Although techniques are cumbersome this is the only precise method of typing now available

PATHOGENESIS

Little is known of the events which allow staphylococci living symbiotically with the human host to become invasive and produce active disease Strains of staphylococci capable of producing infection are common skin inhabitants and more than 50 per cent of serious staphylococcal infections of deep tissue arise from skin lesions A lesser number originate in the respiratory or genitourinary tract

Certain situations are known to predispose to staphylococcal disease *Diabetic patients* have a higher incidence of staphylococcal infections Under circumstances of severe *debilitation* or *malnutrition* in a population staphylococcal infections increase in frequency Staphylococcal infections are common when skin continuity is broken Abrasions wounds burns and skin areas denuded by exfoliative dermatitis are easily infected The incidence of superficial staphylococcal infection is high in individuals who work with greasy skin irritants *Influenza* and *measles* appear to predispose to invasion of the lower respiratory tract by staphylococci Recent studies indicate that broad spectrum antimicrobial therapy by suppression of the normal intestinal microflora occasionally allows the implantation or overgrowth of resistant strains in the gastrointestinal tract with the production of active disease Staphylococci can apparently invade the unbroken human integument via hair follicles and sebaceous glands

At local sites of infection active microbial multiplication is accompanied by inflammation and tissue necrosis Polymorphonuclear cells rapidly enter the area and ingest large numbers of microorganisms Thrombosis of surrounding capillaries occurs fibrin is deposited about the periphery and later fibroblasts create a relatively avascular wall about the area The fully developed staphylococcal lesion consists of a central core of dead and dying leukocytes and bacteria which gradually liquefies to form characteristic thick creamy pus surrounded by a fibroblastic wall the pyogenic membrane

From such an inflammatory focus in the skin staphylococci are often able to enter the blood stream Common sites of metastatic seeding are the diaphyseal ends of the long bones in children the lungs kidneys endocardium liver spleen and brain

Certain biologic properties of staphylococci are thought to contribute to pathogenicity Many strains elaborate an *exotoxin* (alpha toxin) capable of causing dermal necrosis in animals Fever tachycardia cyanosis shock and death ensue when this material is administered to experimental animals by the intravenous route a strikingly similar picture is seen in certain fulminating cases of staphylococcal bacteremia in man

The high correlation between *coagulase* production and virulence suggests that this substance is important in the pathogenesis of staphylococcal infections Although coagulase has been said to protect staphylococci from leukocytes active phagocytosis of coagulase positive staphylococci is readily demonstrable in vitro and in vivo Abscess formation is said to be less common in animal species that lack a coagulable plasma and in infants who show low titers of the serum coagulase reacting factor but the thesis that coagulase is responsible for focal abscess formation has been weakened by the recent demonstration that mice which lack a coagulable plasma develop typical abscesses during staphylococcal infections Recent studies suggest that coagulase may protect pathogenic staphylococci from bacteriostatic substances present in normal serum

Many pathogenic strains of staphylococcus can destroy human or rabbit leukocytes in vitro this has been attributed to a *leukocidin* Some strains produce *hyaluronidase* Many staphylococci are capable of elaborating an *enterotoxin* which produces nausea vomiting and diarrhea in certain experimental animals and in man

It has been established that pathogenic staphylococci can survive and even multiply within human or rabbit leukocytes This finding suggests that these cells may be a means of transporting the organisms and spreading infection to distant tissues

Immunity Clinical observation suggests that some degree of resistance to infection develops with age and perhaps experience with the staphylococcus Primary staphylococcal pneumonia is far

from which invasion of the blood stream can occur

Staphylococcal bacteremia is not a specific entity and manifestations in the individual patient depend upon the original source of the organisms and the site and extent of metastatic infections

Rarely patients with bacteremia die within 12 to 24 hr with high fever tachycardia cyanosis and vascular collapse More commonly the course is slower with hectic fever and progressive involvement of many organs and tissues Abscesses can form in the lungs bones kidneys brain, myocardium liver spleen or any other tissue Pustular or petechial skin lesions are common

The heart valves are often infected producing an endocarditis of the "malignant" or "ulcerative" type in which rupture of valve leaflets and valve ring abscess are common (see p 975) Staphylococcal endocarditis can also run a subacute course that is clinically indistinguishable from that produced by *Streptococcus viridans*

Staphylococcal bacteremia is generally accompanied by a polymorphonuclear leukocytosis of 12 000 to 20 000 but this is not invariable and a normal leukocyte count should never contradict the clinical diagnosis Anemia develops rapidly during the course of the illness

Prognosis Persistent staphylococcal bacteremia is an extremely serious disease Prior to the development of antimicrobials over 80 per cent of individuals succumbed usually within 2 weeks of the onset of illness The sulfonamides did little to alter this fatality rate but the combination of effective antibiotics and appropriate surgical measures results in recovery of 50 to 60 per cent of patients at the present time

STAPHYLOCOCCAL FOOD POISONING

Certain strains of staphylococci produce an enterotoxin which is responsible for many outbreaks of acute gastroenteritis Foods are contaminated from superficial infections in food handlers or by nasal droplets containing pathogenic staphylococci Cream filled pastries custards and cottage cheese subjected to improper refrigeration for a period allowing bacterial multiplication are frequently the source of outbreaks of staphylococcal infection

Symptoms typically appear 1 to 6 hr after ingestion of enterotoxin Onset is abrupt with severe nausea vomiting cramping abdominal pain diarrhea and prostration Low grade fever can occur but most patients are afebrile The disease is brief and self limited and requires only rest replacement of fluid loss and sedation Rare fatalities have occurred in the aged

Diagnosis can be surmised from the short incubation period the epidemic nature of the disease the short duration of symptoms and the lack of fever Etiology can be proved only if specimens of ingested food can be shown to contain large numbers of enterotoxigenic staphylococci

Staphylococcal enteritis a true infection of the gut that sometimes complicates therapy with antibiotics is described on p 1475

MISCELLANEOUS INFECTIONS

Staphylococci may cause otitis sinusitis or mastoid infections Certain strains elaborate an erythrogenic toxin that results in a rash indistinguishable from streptococcal scarlet fever Pyelonephritis and lower urinary tract infections may be staphylococcal in origin Epidemics of staphylococcal pyoderma in newborn infants and maternal breast abscesses are a recurring problem in many clinical maternity units

THE CHANGING PATTERN OF STAPHYLOCOCCAL INFECTIONS

Changes have occurred in the relative incidence of certain staphylococcal infections In prolonging the life span of patients with serious illnesses a group of individuals with increased susceptibility to many infections has been developed The adrenal steroids corticotropins nitrogen mustards and the folic acid antagonists appear to alter host defense mechanisms New surgical procedures have created many new portals of entry for microorganisms In this setting staphylococcal infections (along with gram negative bacillary infections and certain fungous infections) have become an increasing problem

In debilitated hospitalized patients staphylococcal infections are commonly atypical appear to be contracted from hospital personnel and are generally caused by antimicrobial resistant strains of staphylococci

Staphylococcal pneumonia formerly rare now occurs as a terminal complication of many disease states Postoperative wound infections due to staphylococci have increased in frequency Staphylococcal bacteremia arising in the hospital is not uncommon and staphylococcal enteritis is almost exclusively a hospital disease

There is little to suggest that staphylococcal strains resistant to antimicrobials are *any more invasive* than those which have always been prevalent Nevertheless the disease *states in which* staphylococcal infections now commonly arise are often of themselves critical Staphylococcal infec*tions in these* situations continue to carry a high mortality

Rarely the joint capsule is penetrated early and the presenting picture is pyogenic arthritis There is rapid death of bone (sequestration) followed by the laying down of new bone (the involucrum) producing characteristic roentgenographic changes Occasionally indolent staphylococcal infections of bone remain localized within dense granulation tissue about a central necrotic cavity Such a local infection can persist for many years as a so called *Brodie s abscess*

Osteomyelitis in children usually begins abruptly with chills high fever and pain at the local site Muscle spasm about the affected bone is often striking the child may refuse to move the limb and the tissues overlying the bony lesion soon become edematous Roentgenograms are usually normal for the first week but rarefaction local periosteal elevation and new bone formation are generally detectable during the second week of illness

In any patient child or adult with staphylococcal bacteremia secondary infection of bone can occur This tendency of staphylococcal infection to localize in bone is an important consideration in assessing the status of a patient with generalized abscess formation

Diagnosis *Osteomyelitis should be suspected in* any child with fever limb pain and leukocytosis History of a preceding cutaneous infection localized tenderness and the finding of *S aureus* in blood cultures are confirmatory In the early stages osteomyelitis must be differentiated from acute rheumatic fever poliomyelitis scurvy and syphilitic periostitis

Prognosis Prior to the advent of antimicrobials the mortality was approximately 25 per cent Chronic osteomyelitis with recurrent activation and metastatic spread to other bones was common Today acute staphylococcal osteomyelitis is declining in incidence death is rare and chronic osteomyelitis is disappearing

STAPHYLOCOCCAL PNEUMONIA

Staphylococci are the cause of 1 to 5 per cent of bacterial pneumonias The disease is sporadic except for the transient increase in cases that regularly accompanies epidemics of influenza

Primary staphylococcal pneumonia in infants and young children is a frequent cause of pyopneumothorax This complication occurs early in the disease and its presence should immediately suggest *S aureus* as the etiologic agent of a pulmonary infection In older children and adults staphylococcal pneumonia is usually secondary to influenza measles or whooping cough During the past few years staphylococcal pneumonia has come to occur with increasing frequency as a nosocomial infection in hospitalized patients with leukemia mucoviscidosis diffuse collagen disease and other chronic debilitating disorders

Staphylococci generally produce patchy centrally located pulmonary lesions pleurisy empyema and residual parenchymal abscesses are common

Staphylococcal pneumonia usually begins abruptly with repeated chills high fever progressive dyspnea cyanosis cough and pleural pain As in any serious staphylococcal infection peripheral vascular collapse may appear early and examination frequently reveals a patient who seems sicker than the physical findings would suggest Sputum is not characteristic although it may become purulent resembling the contents of a furuncle

Pulmonary infection in the form of multiple abscesses or patchy pneumonia can arise as a result of seeding of the lung from staphylococcal infection elsewhere in the body In primary staphylococcal pneumonia bacteremia is demonstrable in only about 20 per cent of cases It is far more common to obtain positive blood cultures if the lung lesions are secondary to bacteremic spread from another site For this reason the finding of staphylococcemia in a patient with pneumonia should lead to a *vigorous search for a primary focus of infection* in another organ

Diagnosis The sputum contains masses of polymorphonuclear leukocytes and bacteria The finding of numerous intraleukocytic cocci in stained smears of sputum strongly suggests the diagnosis The blood leukocyte count usually exceeds 15 000 with a marked increase in immature granulocyte forms but an initial leukopenia can occur Blood cultures are positive in less than 20 per cent of cases

Suddenly developing pneumonia with high fever and leukocytosis in debilitated hospitalized patients receiving antimicrobials should be considered staphylococcal in origin

Prognosis Prior to 1942 mortality ranged from 50 to 95 per cent The presence of bacteremia was almost invariably associated with a fatal outcome Prognosis has improved with the use of antibiotics but from 15 to 50 per cent of patients fail to survive The tendency to abscess formation and the frequency of pleural infection prolong convalescence in many patients

STAPHYLOCOCCAL BACTEREMIA

Staphylococcal bacteremia can originate from any type of local staphylococcal lesion Trauma to local lesions pinching squeezing or even surgical drainage often precipitates transient bacteremia with subsequent spread of infection multiple abscess formation and the creation of additional sites

continued for a minimum of 4 weeks and should be extended to 6 weeks to 3 months in the management of staphylococcal endocarditis

Superficial Infections Any of the antistaphylococcal drugs may abort the full development of a furuncle if treatment is initiated before localization and central necrosis have occurred Once frank abscess formation has ensued antimicrobials do little to modify the local lesion although they may prevent secondary superficial lesions or blood stream metastasis Antimicrobial drugs should be continued for 10 to 14 days if administered and should be used in conjunction with local moist heat immobilization of the affected part and strict attention to soap and water cleanliness Local manipulation of the lesion should be avoided unless surgical drainage is required Moist heat should be discontinued when drainage occurs to prevent maceration of the surrounding skin and the development of secondary furuncles The surrounding skin should be protected with a heavy coating of zinc oxide during the drainage period The use of topical antimicrobial creams (tyrothricin neomycin bacitracin) about the furuncle has been suggested to prevent satellite seeding *Bouts of recurrent furunculosis are difficult* to control sometimes they can be aborted by the administration of penicillin or other antistaphylococcal agents in full doses for 2 to 3 weeks in conjunction with general hygienic measures

Empyema Empyema should be treated by aspiration and the instillation of 200 000 to 500 000 units of penicillin every 24 to 48 hr Streptomycin 200 to 1 000 mg may also be instilled If loculation and thick exudate prevent adequate needle drainage the local instillation of streptokinase and streptodornase may aid in liquefying the exudate The removal of exudate is the most important aspect of therapy and surgical drainage should be promptly performed if the above measures fail

Osteomyelitis Acute osteomyelitis generally responds promptly to antimicrobial therapy Aqueous *penicillin 300 000 to 1 000 000 units should* be given every 4 hours and continued for 14 to 28 days

If the illness is rapidly progressing or an antimicrobial resistant strain is suspected streptomycin or erythromycin should be administered along with penicillin Bacitracin may be of value in certain cases Local drainage of abscess cavities in the soft tissues or bone is sometimes required and should be promptly considered in all patients where response to antimicrobials is inadequate or delayed *Sequestration should be handled surgically*

113 HEMOLYTIC STREPTOCOCCAL INFECTIONS (Including Rheumatic Fever and Glomerulonephritis)

Charles H Rammelkamp Jr

Advances in the knowledge of streptococcal infections in the past few decades have made it increasingly clear that aerobic streptococci as a group are probably among the most important bacterial pathogens for man These bacteria may invade any tissue or organ and depending on the site of invasion and the parasite host relationship produce different clinical syndromes *Streptococcal* infections may be divided conveniently into two large groups The acute and often dramatic illnesses such as sore throat scarlet fever erysipelas puerperal fever and lymphangitis are included in the first group These infections occur *frequently and are characterized by* certain toxic septic or suppurative features The second group of diseases have been called the late nonsuppurative complications of streptococcal infections These illnesses which include acute rheumatic fever and acute glomerulonephritis commonly become manifest 2

TREATMENT

Features of Staphylococcal Infections Which Influence Therapy Certain features of staphylococcal infections bear emphasis in considering therapy

1 Staphylococci produce rapid necrosis and destruction of tissues Delays in effective therapy may convert an acute reversible illness into a chronic suppurative disease which responds slowly if at all to antimicrobial therapy

2 Frank abscess formation is common Antimicrobials of any type are almost completely ineffective in the presence of extensive necrosis or suppuration Successful cure frequently depends on prompt surgical drainage of all accessible suppurative foci

3 Staphylococci are killed slowly by antimicrobials under even optimal circumstances Infections tend to become chronic and relapses are frequent when therapy is withdrawn Thus antimicrobial therapy should be continued longer than in many bacterial infections

4 The changing patterns of staphylococcal antibiotic susceptibility have made in vitro sensitivity tests of great importance in the choice of appropriate antibiotic agents No single antimicrobial regimen has been found universally effective

Initial Treatment of Systemic Infections When serious staphylococcal infections are suspected appropriate cultures should be obtained and treatment started immediately with aqueous penicillin 500 000 to 2 000 000 units intramuscularly every 2 hr Surgical drainage of local foci should be carried out promptly When staphylococcal infection has arisen within the hospital or in other situations in which antimicrobial resistant strains are common a companion antimicrobial agent should be administered concurrently The choice of a companion drug will depend in part on the nature of the antimicrobial resistant strains prevalent within a given community Erythromycin and chloramphenicol 2 to 4 Gm daily in divided doses by the oral route are currently the companion drugs most frequently used at the New York Hospital because of the high incidence of strains sensitive to these agents in vitro In many hospitals erythromycin is reserved primarily for use in serious staphylococcal infections to reduce the hospital spread of erythromycin resistant strains and thus preserve its effectiveness

Changes in Therapy Established staphylococcal infections respond slowly to even the most effective antimicrobial regimens making it difficult to know when therapy should be considered inadequate Characteristically 24 to 48 hr elapse before a decline in fever is noted and recovery is accompanied by slow return of the temperature to normal in 7 to 10 days If the disease process shows evidence of rapid progression during the first 24 to 48 hr of treatment or if fever remains high for over 96 hr in the absence of detectable abscess formation antimicrobial therapy should be revised

While in vitro sensitivity studies are of great value the clinical response of the patient is the most important index on which to base changes in antimicrobial therapy If the response to initial therapy is satisfactory it should be continued regardless of in vitro evidence of resistance of the staphylococcus isolated If changes in therapy are indicated by the clinical course other antimicrobials should be selected on the basis of their in vitro activity against the strain under treatment.

Other antimicrobial drugs which have been found of value in the management of staphylococcal infections include the tetracyclines streptomycin novobiocin and bacitracin All these agents plus erythromycin and chloramphenicol have been used successfully alone or in various other combinations in the treatment of certain staphylococcal infections

Erythromycin and chloramphenicol administered together are currently used as the primary treatment of serious staphylococcal disease in some hospitals Streptomycin or dihydrostreptomycin 2 Gm daily has been a useful antistaphylococcal agent when used in conjunction with large amounts of aqueous penicillin The tetracyclines in 2 to 4 Gm daily doses are effective in the treatment of infections due to susceptible strains

Most strains of staphylococci now isolated (1957) are sensitive to novobiocin and this drug has been valuable when used alone or together with other antibiotics in selected staphylococcal infections Certain serious antimicrobial resistant staphylococcal infections have responded to bacitracin alone 15 000 to 25 000 units given every 6 hr or to bacitracin in combination with penicillin or streptomycin Bacitracin should not be used where renal impairment is evident and should be halted if evidence of declining renal function follows its use

The use of two or more antimicrobial agents concurrently has arisen from two considerations (1) the large number of therapeutic failures with any single antibiotic has led to the use of multiple drugs because of an unwillingness to withhold any agent of possible benefit to the patient (2) there is in vitro evidence that the emergence of resistant strains can be delayed by the simultaneous use of two or more antibiotics

It should be noted that to date there is no convincing proof that combined antibiotic therapy is superior in treatment of staphylococcal infections and that increasing resistance of strains in deep seated staphylococcal infections under treatment is actually rare

The therapeutic regimens outlined above apply to the management of staphylococcal pneumonia bacteremia and endocarditis Treatment should be

The exact role of streptokinase in the infectious process is not known The spreading nature of streptococcal infections has been thought to be due to streptokinase which breaks down the fibrin barrier

Following infection in man by a strain of group A streptococcus which produces large amounts of streptokinase antibody usually develops which specifically prevents the lysis of fibrin Thus the measurement of antistreptokinase may aid in diagnosis This serologic test is not so useful a diagnostic tool as the antistreptolysin test because not all group A streptococci produce sufficient streptokinase to stimulate antibody formation

Streptodornase (desoxyribonuclease) is an enzyme produced by several groups of streptococci This enzyme depolymerizes desoxyribonucleoprotein and desoxyribonucleic acid the two substances which account for the high viscosity of exudates A preparation of streptokinase streptodornase (SK SD) is now available for injection into body cavities containing pus or blood Such therapy results in the liquefaction of the fibrin and cellular debris

Other substances produced by streptococci are leukocidin hyaluronidase and streptococcal proteinase Leukocidin which is probably identical with streptolysin O is able to inhibit phagocytosis in vitro The enzyme hyaluronidase or spreading factor undoubtedly facilitates the spread of bacteria by increasing tissue permeability It is produced in large quantities by types 4 and 22 of group A streptococci

ACUTE STREPTOCOCCAL INFECTIONS

Epidemiology

Aerobic streptococcal infections are observed in all races in both sexes and at all ages Furthermore they occur during any season of the year throughout the world The *incidence* and the *clinical manifestations are altered by certain of the above factors* Thus streptococcal respiratory infections including scarlet fever are encountered especially during the colder months of the year Scarlet fever is rare in the tropics Under the age of three months streptococcal infections are rare and when they occur are associated with a high mortality Between the ages of six months and ten years scarlet fever is prominent Tonsillitis and pharyngitis are especially prevalent throughout childhood and early adult life In the female during the child bearing period puerperal infections caused by streptococci are occasionally observed Finally erysipelas which may occur at any age appears to be more prevalent in infants and the older age groups

Soon after birth alpha streptococci appear in the upper respiratory tract and may be isolated there from throughout life Streptococci of Lancefield groups C and G and more rarely organisms of groups other than A may be isolated from the oropharynx of 5 per cent or more of the normal population Occasionally group C and G streptococci cause tonsillitis

The group A flora of the oropharynx of any population group is made up of many different specific types but usually several types predominate In general at least 5 per cent of the people of any community harbor group A streptococci The prevalence varies and depends upon the cultural methods used as well as upon environmental host and bacterial factors Persons under twenty years of age especially if the tonsils are present are most likely to harbor group A streptococci

Studies of carriers of group A streptococci suggest that many are convalescent carriers that is they recently suffered either an apparent or an unapparent infection This appears to be especially *likely if large numbers of streptococci are isolated* from the oropharynx Such individuals frequently give a history of a recent illness and the antistreptolysin titer of their serum is high These data suggest that streptococci of group A rarely occur in the throat in large numbers except immediately before during or after an infection Once an individual has been infected he may remain a carrier for many months As the carrier state progresses the streptococci lose their ability to produce M protein

Ability to spread disease appears to be an attribute of individuals who have recently been infected Whether this is because such persons harbor numerous streptococci in the nose and throat or because the organisms are especially capable of parasitizing another person cannot be determined from the available evidence It is established that nasal carriers of group A streptococci are especially likely to spread disease

Respiratory pathogens are believed to be spread by two mechanisms (1) *directly* between two persons by *physical contact or by droplets passing* through the air for short distances (2) *indirectly* by droplet nuclei dust and fomites Recent studies have shown however that group A streptococci naturally deposited in dust and on blankets will not produce respiratory infections in man The evidence implicates the direct mode of transfer as primarily responsible for dissemination of such infections

The spread of streptococci in any population group must also be related to the degree of exposure Thus during the winter months when people are confined to enclosed areas and under crowded conditions dissemination of bacteria is especially likely to occur

Outbreaks of streptococcal infection occasionally *occur following the contamination of food* Such

to 3 weeks after an acute streptococcal infection These diseases assume major importance because they may be followed by chronic valvular heart disease or possibly by chronic nephritis

History Although scarlet fever was recognized in 1676 by Sydenham rheumatic fever and acute nephritis were not well described until 1805 and 1836 respectively The role of the streptococcus as the inciting agent of scarlet fever was established in 1924 With the realization that rheumatic fever and nephritis were related to streptococcal infections methods for the control and management of these nonsuppurative complications developed rapidly

Bacteriology Streptococci are gram positive and tend to form chains When streptococci are grown on a sheep blood agar plate it is possible to divide them into three groups *Alpha* colonies show a zone of incomplete or green hemolysis *beta* streptococci exhibit a clear zone of complete hemolysis and finally *gamma* streptococci produce no visible change in the blood agar Such a simple procedure as streaking a culture on a blood agar plate is sufficient to indicate the important pathogenic streptococci because those exhibiting *beta* hemolysis are responsible for the majority of infections in man

On the basis of a specific carbohydrate 12 groups of streptococci have been identified and designated A B C D E F G H K L M and N Respiratory infections are caused by group A and only rarely by groups C and G streptococci Group D streptococcus previously referred to as *Streptococcus faecalis* or enterococci inhabits the gastrointestinal tract and is responsible for infections of the abdominal cavity and the urinary tract

Not only may streptococci be classified by grouping but also most groups contain several different types Group A of primary interest to the clinician comprises at least 40 specific types Typing is based either on an agglutinin reaction or on the precipitin test The type specific antigen is the T substance in the former method the M substance in the latter

By grouping and typing streptococci considerable information has been accumulated concerning streptococcal infections from both a theoretic and a practical standpoint The carbohydrate responsible for the group characteristics is nontoxic and unassociated with virulence or immunity In contrast the M protein which tags the organism as the polysaccharide tags the pneumococcus is identified by typing is antigenic and is probably responsible in part for the virulence of the organism as well as for type specific immunity Glossy forms of group A streptococci which contain no M substance are avirulent whereas virulent organisms always contain this specific protein The T substance is not related to virulence

Several substances produced during the growth of beta streptococci serve to differentiate these organisms from other streptococci as well as to explain in part their pathogenic effects The type of hemolysis has been used as described above for classification of these bacteria Of the various hemolysins produced by streptococci at least two types have been recognized and termed *streptolysin O* and *streptolysin S* They are produced by streptococci of Lancefield groups A C and G the three organisms which cause the majority of human infections The role of these hemolysins in infections in man is not definitely known but they may be responsible for the anemia observed during the course of certain streptococcal diseases In man infections due to streptococci of groups A C and G result in the production of antistreptolysin O Approximately 85 per cent of patients develop antistreptolysin O during the second to third week of convalescence It is apparent then that the determination of the antistreptolysin titers of acute and convalescent serums may establish the diagnosis since an increase in titer occurs following a streptococcal infection

Another filtrable toxin produced by group A streptococci is the erythrogenic or *scarlatinal toxin* It is so named because it causes a scarlatiniform rash when injected into man and if sufficient quantities are given there may be fever and nausea That this toxin is responsible for the rash and toxic features of scarlet fever is well established Trask and Blake were able to demonstrate a toxin in the circulating blood of patients with scarlet fever and showed that it was neutralized by specific antitoxin Using the erythrogenic toxin as an antigen a skin test for susceptibility to scarlet fever was developed by the Dicks When one skin test dose is injected intradermally persons susceptible to the erythrogenic toxin respond with an area of erythema which reaches its maximum within 24 hr Persons exhibiting this skin reaction are susceptible to scarlatiniform rashes when infected by streptococci which produce erythrogenic toxin It should be emphasized that individuals exhibiting a negative Dick skin test although generally immune to scarlet fever are not immune to infection by group A streptococci The occasional occurrence of second attacks of scarlet fever may be explained by the fact that there are at least two types of immunologically distinct erythrogenic toxins

In 1933 it was observed that hemolytic streptococci rapidly liquefied human fibrin The extracellular substance responsible for this action is termed *streptokinase* Streptokinase does not lyse the fibrin directly but activates a serum enzyme plasminogen which in turn lyses the clot Streptokinase is produced by strains of Lancefield groups A C and G and only occasionally in small amounts by groups B and F

Pathogenesis

Streptococci gain entrance to the body primarily through the upper respiratory tract The organisms lodging on the mucous membranes or on other tissues probably remain viable for relatively short periods unless they actually invade the tissues In the nose and throat there is ample opportunity for invasion The organisms usually gain entrance through the lymphoid tissues of the throat especially the tonsils whose crypts apparently offer an ideal locus Occasionally the primary infection may be in the paranasal sinuses

The factors which determine whether an infection follows exposure to the organism are multiple The *dosage* or number of streptococci is apparently a decisive factor Infection usually results when there is exposure to large numbers of group A streptococci as occurs in food borne outbreaks Under natural conditions of spread the number of organisms acquired is dependent in part on the duration and intimacy of exposure to the organism

The second factor in relation to the organism is *virulence* In general little is known concerning this important feature Streptococci of groups other than A may be considered relatively avirulent when implanted in the lymphoid tissues of the throat The virulence of the group A organism may be related to their M antigenic component Whether there is variation in the virulence of the group A streptococci according to the specific type is not definitely known nor is there much evidence that rapid passage of a given type from man to man increases the virulence of the organisms although this is a common belief

Perhaps as important as the organism itself is the susceptibility of the host It is stated that a recent or simultaneous infection with one of the common respiratory viruses renders the host more susceptible to bacterial invasion Experience during the First World War would seem to indicate that influenza does indeed make one more susceptible to bacterial infections Whether the common cold or acute respiratory disease acts in a similar fashion is not known

Whether the group A streptococcus gains a foothold in the tissues is also governed by the immune status of the host The presence of type specific antibodies undoubtedly protects the individual against invasion by the streptococcus

When the bacteria begin to multiply in the infected tissues they produce certain toxic substances which account for the clinical manifestations of disease For example some of the constitutional symptoms observed in patients with scarlet fever are believed to be due to the erythrogenic toxin Usually the mucous membrane is denuded and covered by a thin yellow white or gray exudate Edema and hyperemia of the lymphoid tissues are present The lymphatics are dilated The regional cervical lymph nodes are enlarged

The organisms may invade the blood stream if the local defense mechanism is not functioning adequately and cause either metastatic infections such as meningitis brain abscess and endocarditis or a generalized infection which without treatment almost invariably results in death Mallory and Keefer have studied the cellular changes in such patients as well as the disease process in patients dying during the acute phase of streptococcal infections without bacteremia In fulminating streptococcal infections the streptococci may be seen in blood vessels throughout the body as well as in the endothelial cells of the endocardium and in the perivascular areas There is little cellular reaction around the organisms but their distribution is similar to the distribution of those lesions observed in patients dying several days after onset of the infection In the latter cases foci of lymphocytes plasma cells and histiocytes are commonly found in the heart especially just under the surface endothelium and endocardium Such collections occur also in the perivascular connective tissues myocardium and pericardium Occasionally some of the foci show polymorphonuclear leukocytes In the kidneys interstitial nephritis is observed with focal areas of round cell infiltration in the tissue surrounding the tubules glomeruli and blood vessels Similar lesions may be observed in other organs including the lung portal areas of the liver and pancreas

Most streptococcal infections are of short duration the acute phase ending within 5 to 7 days The exact mechanism for recovery at this time has not been defined but as in other bacterial infections it is assumed that antibodies develop which aid in the destruction of the organism Perhaps the most important of these are the antibacterial substances Techniques for measuring these antibodies are difficult but it is apparent that following infection there is an increase in the bactericidal power of whole blood Such bactericidal action is type specific the patient is protected only against the infecting type of group A streptococci and not against other types of this group of organisms The duration of such antibacterial immunity is not known but recent studies have demonstrated antibodies for 5 to 10 years

Clinical Manifestations

Acute Tonsillitis Pharyngitis and Scarlet Fever

The terminology used to classify *streptococcal* infections of the upper respiratory tract has been in use for many years and was introduced *prior to* the time that it was realized that *scarlet fever* sep

outbreaks are dramatic in that a large number of persons are affected almost simultaneously Formerly this type of infection was termed *septic sore throat* aside from the fact that the infection is caused by a single type of streptococcus it varies clinically in no way from other streptococcal epidemics

Clinical studies have demonstrated that reinfection may occur by a second type of group A streptococcus in a patient recovering from streptococcal pharyngitis and tonsillitis

Primary infection of the upper respiratory tract is undoubtedly the most common form of streptococcal infection in man It is doubtful whether any one in the United States escapes one or more of these infections The disease occurs especially in individuals between the ages of one and twenty years but it may develop at any age It is especially prevalent in the Temperate Zones during the winter and early spring seasons In most areas the disease is endemic Epidemics are usually due to one or at the most several types of group A streptococci whereas many different types are responsible for cases of pharyngitis and tonsillitis occurring sporadically

Tonsillitis and *pharyngitis* due to the beta streptococcus are characterized by an acute sore throat which may or may not be accompanied by a cutaneous rash If a rash is observed a diagnosis of *scarlet fever* is made The occurrence of a rash is related to antitoxic immunity which may be measured by the Dick test

Studies of the Dick reaction in various population groups have shown that at birth and up to three months of age the test is usually negative By the age of one to two years 85 per cent of the reactions are positive There is a rapid decline in the positive reactors to a level of approximately 15 per cent at the age of ten During the rest of life the decline is gradual These results would indicate that children under the age of ten are most susceptible to scarlet fever and this is the age period when most scarlet fever occurs Following an attack of scarlet fever the Dick reaction usually becomes negative

The incidence of scarlet fever has not changed significantly in the past 30 years but there has been a spectacular decline in mortality Top reports a fatality rate in Detroit of 2 7 in 1920 1 3 in 1930 and 0 3 in 1940 The reason for the apparent decreasing severity of scarlet fever is not entirely clear

Infections of the *paranasal sinuses* and middle ear often develop following infection of the tonsils or pharynx Not only may they occur as a complication of streptococcal sore throat but they are also commonly seen following measles influenza pertussis and other respiratory infections

Bacterial pneumonia caused by aerobic streptococci accounts for less than 5 per cent of all cases of pneumonia The disease is almost invariably caused by group A streptococci and may arise secondarily to an infection of the upper respiratory tract Epidemics have been observed following influenza and measles It also is likely to occur in those individuals with chronic lung disease including asthma and bronchiectasis Streptococcal empyema a complication of pneumonia in most instances is observed most frequently in patients under thirty years of age

Formerly it was thought that *erysipelas* was caused by a specific strain of beta hemolytic streptococcus but it is now known that group A C or G streptococci may be isolated from the skin lesions Group A organisms are responsible for the majority of infections and the organisms may belong to any of the various types in this group Although there are examples of several people having contracted erysipelas following contact with a case in most instances it has been impossible to trace the infection to such contact Erysipelas tends to occur in the older age groups especially in those individuals with chronic disabling diseases Immunity does not develop in fact individuals who have suffered from one attack are more susceptible than the normal population In some of the recurrences however the organisms cannot be isolated from the skin lesions but may be found in the oropharynx It is suggested that in such instances the disease is due to absorption of some toxic product of the streptococcus which in turn causes the local inflammatory lesion in the skin that is altered in its reactivity

Wounds may be infected by contamination at the time of dressing by droplets from either the patient or the attending physician Another possible source of infection is dust *Lymphangitis* may arise from a minute abrasion

Numerous studies have indicated that either aerobic or anaerobic streptococci cause *puerperal sepsis* Approximately 70 per cent of fatal cases are due to beta hemolytic streptococci Most of the infections are caused by group A although an occasional case is due to streptococci belonging to group B C D or G Since the group A streptococcus is rarely isolated from the genital tract either before or after labor it is assumed that infection is extrinsic Careful study of the patient and all persons coming in contact with her has shown that similar types of group A streptococci can be isolated from 75 per cent of cultures obtained from the oropharynx of such a patient or those attending her It appears from these studies that infection is usually contracted from an outside source and occasionally from the respiratory tract of the patient herself

Course of Illness (Fig 137) The majority of upper respiratory illnesses caused by group A streptococci are self limited In adults the temperature usually returns to normal by the third to fourth day whereas in children fever may persist for 5 to 9 days The temperature curve is not characteristic, although there is usually a slight morning remission In patients with scarlet fever the temperature remains elevated until the rash has reached its maximum intensity Fever may last for several weeks but in such instances it is well to search for some suppurative complications The constitutional symptoms as well as the localizing symptom of sore throat usually disappear shortly after the fever subsides

The edema redness and exudate disappear rapidly and except for a few small isolated spots of exudate and a slight degree of redness the throat appears essentially normal shortly after the fever subsides The lymphoid tissues of the posterior pharynx as well as the tonsils decrease in size and by the third to sixth week appear to be normal The lymph nodes may not return to normal size for 6 weeks

When rash does occur it usually makes its appearance on the second day reaches its maximum intensity shortly thereafter and then begins to fade The exfoliation of the epithelium begins during the decline of the eruption and is seen first in those areas where the rash originally appeared By the sixth to seventh day it is more or less generalized On the hands and feet the skin sheds in flakes or more rarely an entire cast of the hand or foot may be observed The skin in these areas becomes dry hard and wrinkled The most typical form of desquamation is seen beneath the free edge of the fingernails A fissure appears under the edge of the nail and then widens revealing the soft pinkish underlying skin

Before the introduction of specific chemotherapeutic agents the mortality rate was in the neighborhood of 3 per cent it is now less than 0 5 per cent This may be because of treatment or because few severe forms of scarlet fever are seen today Streptococcal infections are likely to be fatal in the extremes of life and in those individuals with severe suppurative complications

Laboratory Findings In 80 per cent of patients the total leukocyte count is increased During the first 2 days of disease the average count is 14 000 and as the illness progresses it returns to normal values If the number of leukocytes remains elevated after 1 week evidence of a complication may be found During the first 2 days of illness eosinophils are rarely seen but convalescence is characterized by an increase of these cells Patients with scarlet fever are especially likely to exhibit an elevation of eosinophils Not infrequently a trace

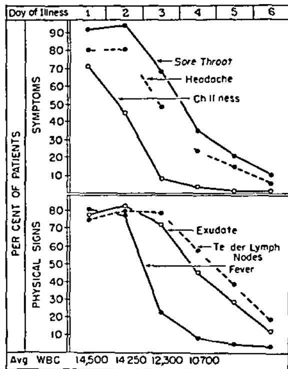

Fig 137 The natural course of group A streptococcal tonsillitis

of albumin may be found in the urine during the acute phase of the illness Rarely such specimens show a few red cells or casts Proteinuria occurring during the first 5 days of illness is transient and is not attended by serious sequelae

Cultures made on blood agar plates from a swab rubbed over the tonsils and oropharynx usually show a predominant growth of beta hemolytic streptococci Occasionally only a few colonies are observed Rarely no streptococci are isolated In the latter instance repeated cultures should be obtained The convalescent carrier state may continue for several months

Diagnosis Important features in the diagnosis of streptococcal pharyngitis and tonsillitis are the history of an acute onset of soreness on swallowing associated with feverishness and other constitutional symptoms The physical signs of diffuse redness and edema of the mucous membranes of the oropharynx tonsils and soft palate the presence of discrete to confluent exudate and enlargement and tenderness of the lymph nodes at the angle of the jaw are especially helpful These findings together with a leukocyte count of at least 12 000 suggest a streptococcal infection If the culture of the local lesion shows a predominant growth of beta streptococci the diagnosis is almost certainly established When only a few colonies grow on the blood agar

tic sore throat acute tonsillitis and *pharyngitis* with or without exudate were all caused by any of the numerous types of group A streptococci In these diseases the organism establishes itself in the lymphoid tissue *streptococcal lymphoiditis* might well be substituted for the above names As far as is known the course of the illness complications and sequelae are similar in scarlet fever septic sore throat and streptococcal tonsillitis

Symptoms The incubation period varies from 1 to 10 days but is usually 3 to 5 days The illness begins abruptly in most cases with symptoms of feverishness chilliness headache and sore throat Nausea and vomiting are especially common in children A few patients complain of diarrhea Within a period of 24 to 48 hr the disease reaches its maximum intensity Chilliness is a constant symptom but true rigors are rarely observed Approximately 75 per cent or more of the patients complain of such constitutional symptoms as headache malaise and loss of appetite

The symptom which is very annoying and almost constantly present within 24 hr of onset is sore throat The soreness is aggravated by swallowing and may be referred to the neck so that even turning of the head is accompanied by pain Nasal obstruction and discharge are minor complaints but occur in 60 per cent of patients About half the patients develop very mild symptoms referable to the lower respiratory tract including cough and hoarseness The cough is not productive and is rarely associated with chest pain Loss of voice due to laryngitis does not occur Earache is common and may last a few hours to several days Occasionally epistaxis is observed

During the period of maximum temperature there may be a diffuse blush of the skin In some cases it becomes more pronounced and a diagnosis of *scarlet fever* is made The rash may appear from 1 to 5 days after onset of illness and is first noticed over the neck and upper chest It spreads rapidly to include the skin over the abdomen and upper and lower extremities The face appears flushed and a circumoral pallor is prominent in many cases Itching occasionally occurs but is rarely severe

Physical Signs The degree of prostration varies but the majority of patients appear mildly or moderately ill The temperature is usually elevated to 102 to 104 F occasionally it may be as high as 106 F A few patients have no fever In children the pulse rate is between 140 and 160 in adults between 120 and 140 per minute Usually the respirations are not greatly increased

Various degrees of diffuse redness of the mucous membranes of the posterior pharynx faucial tonsils and soft palate are invariably present The uvula is frequently edematous as are the tonsils and pharynx but to a lesser degree Lymphoid hyperplasia and edema which gives the posterior pharynx a cobblestone appearance are present Characteristically there is discrete to confluent exudate on the tonsils and variable numbers of pinhead size areas of exudate appear on the pharynx In severely ill patients the latter are seldom seen because nasal secretions cover the posterior wall The exudate is often yellow sometimes gray or white and is relatively easily removed by swabbing In about 20 per cent of adults and more frequently in infants exudative lesions on the mucous membranes do not develop Occasionally and especially if sinusitis and rhinitis are coexistent there is a thick mucopurulent nasal discharge which may be tinged with blood In children the nares may be excoriated The cervical lymph nodes are swollen and frequently tender The lymph nodes just below the angle of the jaw are the first to enlarge rarely they attain such size that the head is thrown back Marked adenopathy is frequently followed by suppuration

In those patients with *scarlet fever* the signs include both an enanthem and an exanthem The appearance of the throat is similar to that seen in tonsillitis and pharyngitis without rash except that diffuse redness is more intense and has been described as boiled lobster" red There may be punctate redness of the soft and hard palate The buccal mucous membranes appear red and swollen as do the lips About the second to fifth day small milk white patches may be seen on the buccal mucous membranes They represent desquamation of the epithelium and are easily peeled off

Early in the course of the infection the tongue is heavily coated and grayish Soon the tip and edges become an angry red Fungiform papillae become swollen and emerge through the gray surface of the tongue By the fourth to fifth day there is complete lingual desquamation which leaves multiple papillary elevations the so called "strawberry tongue

The color of the exanthem varies and has been described as scarlet bright red rose colored or dull dusky red At a distance there appears to be a uniform blush but upon close inspection innumerable small reddish points are seen Because of pin point elevations at the site of the hair follicles the skin may feel like sandpaper This sign is of special importance in races where the skin is heavily pigmented When the eruption is intense there may be many small miliary vesicles over the chest and abdomen The face may be free of rash but ordinarily the temples and cheeks are deep red leaving an area of pallor around the mouth and nose The rash is due to hyperemia and pressure causes it to fade In some areas there may be punctate hemorrhages which do not fade these are commonly seen in the creases at the elbow flexure (Pastia s sign) groin and axillary folds

nasal discharge persists it is usually indicative of sinus infection Individuals with this type of involvement may expel tremendous numbers of streptococci into their environment and thereby give rise to numerous secondary infections

The symptoms of acute streptococcal sinusitis other than purulent discharge are fever headache and pain The headache may be suboccipital when the sphenoid is involved or temporal and supra orbital when the ethmoid is involved Fever continuing after the fourth or fifth day of acute pharyngitis should suggest sinusitis There may be edema and redness over the maxillary or frontal sinuses and tenderness over those areas is elicited by slight pressure The diagnosis is established by culture of the discharge direct visualization of the nasal cavity and by transillumination and roentgenograms

A very common suppurative complication of streptococcal infections of the upper respiratory tract is involvement of the middle ear *Otitis media* may be unilateral or bilateral The two cardinal symptoms are fever and pain in the ear In a few adults and especially in children these symptoms may be absent Fever may develop suddenly and in the young is apt to be associated with nausea, vomiting loss of appetite and irritability The temperature tends to be irregular ranging between 102 and 103 F In older children and adults severe pain is almost invariably present Infants who can not complain of pain, may refuse to lie on the affected side or may pull the ear With involvement of the mastoid cells pain is intense and the fever is high

The physical signs of middle ear infection include tenderness around the ear inflammatory changes in the tympanic membrane and discharge The auricle itself sometimes is tender Early in the infection the tympanic membrane is injected and red later it may bulge at which time the landmarks become obliterated Finally if the process does not resolve rupture occurs

Mastoiditis usually arises in patients with otitis media but occasionally it may develop without an apparent infection of the middle ear The skin overlying the mastoid cells becomes red and swollen and the posterior wall of the external auditory canal may be involved The swelling may be so extensive that the auricle is pushed forward Early roentgenograms show no abnormalities but as the disease progresses cloudiness and destruction of the mastoid cells occur The continuation of fever in patients with a draining ear suggests mastoiditis Paralysis of the sixth cranial nerve and deep orbital pain indicate spread to the petrous cells Chills and septic fever suggest invasion of the blood stream thrombosis of the lateral sinus or meningitis

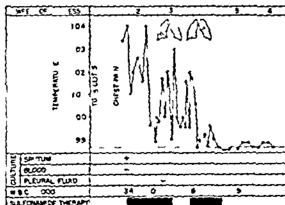

Fig 138 Streptococcal pneumonia with a sterile pleural effusion developing after an attack of acute tonsillitis

Peritonsillar Abscess

Complications of streptococcal sore throat are cellulitis and abscess formation around the tonsils In young children these lesions appear in the retropharyngeal areas Although these complications not infrequently follow a Lancefield group A infection similar abscesses may be caused by other organisms Characteristically the patient recovers from the acute throat infection only to complain a few days later of soreness on swallowing and difficulty in opening the mouth Trismus is caused by edema and spasm of the pterygoid muscles Fever may recur but in some instances it is absent Examination early in the course of illness shows diffuse redness and edema of the anterior pillar the tonsillar fossa, and the soft palate on the involved side As the disease progresses abscess formation may become apparent, and an area of fluctuation may be felt at the superior pole of the tonsil At this time the pain is intense Spontaneous rupture or surgical drainage is followed by rapid relief of symptoms

Pneumonia and Empyema

The natural course of pneumonia caused by Lancefield group A streptococci is extremely variable probably because in many instances it is secondary to such infections as influenza tonsillitis measles and erysipelas It may be associated with pneumococcal infection of the lung or may arise as a metastatic complication of streptococcal bacteremia Although it is not a common complication of streptococcal sore throat, about 25 per cent of pneumonia cases follow this infection (Fig 138) Characteristically this organism produces an interstitial or confluent pneumonia The reported mortality rate varies from 15 to 60 per cent

The onset of pneumonia may be abrupt, with such constitutional symptoms as chills feverishness anorexia and vomiting Symptoms include cough expectoration of purulent sputum, and chest pain

plate it is impossible to be sure whether the patient is a carrier or actually has an infection due to the streptococcus In such cases it is of considerable help to obtain acute and convalescent blood specimens for determination of the antistreptolysin titer

When a rash is associated with the above clinical and laboratory findings the diagnosis is scarlet fever Confirmation is obtained if later the skin desquamates Occasionally however the diagnosis is doubtful and in such cases the Schultz Charlton test may be of considerable aid In this test 0 1 ml scarlet fever antitoxin or 0 2 to 0 5 ml scarlet fever convalescent serum is injected subcutaneously into the area of the skin where the heaviest rash appears If the rash is due to the erythrogenic toxin blanching is observed within 2 to 8 hr The test should be employed soon after the eruption appears because blanching may not occur after the second day of rash The Dick test may also be of some use in establishing the diagnosis early in the disease it is positive whereas during convalescence it usually becomes negative

Nonbacterial exudative tonsillitis and pharyngitis must be differentiated from streptococcal infections of the oropharynx (see p 1044) The agents responsible for these infections have not been completely defined but it is known that some of the adenoviruses will produce respiratory infections associated with exudative lesions and in some outbreaks there is involvement of the conjunctiva In general the onset of illness is not rapid soreness of the throat is seldom marked and constitutional symptoms are mild Hoarseness and cough are likely to occur several days after the onset The exudate is rarely confluent Diffuse redness and edema of all the mucous membranes are rare The lymph nodes may be slightly enlarged but they are not remarkably tender

The leukocyte count is usually normal, although in a few cases it may be slightly elevated Cultures of the throat fail to show beta hemolytic streptococci Occasionally a few streptococci are recovered but these organisms usually belong to groups other than A and occur only in small numbers

Infectious mononucleosis is most frequently observed in young adults and because of the local reaction in the throat is likely to be confused with streptococcal pharyngitis (see p 1151) The onset may be insidious and malaise is prominent Sore throat with exudative lesions of the tonsils is observed in over half the cases The exudate is usually white and pasty and persists for 1 to 3 weeks The temperature tends to be very irregular and fever continues for a longer period than is usual in streptococcal infections Lymph node enlargement is more generalized but suppuration is not observed The spleen may be palpable In 10 to 15 per cent of cases a fleeting skin rash occurs which may be identical with that seen in scarlet fever In such cases a negative Schultz Charlton test may be helpful The blood changes are characteristic and a positive heterophil antibody test is usually obtained

Vincent's angina is not easily confused with streptococcal infections The disease is characterized by insidious onset without constitutional symptoms Fever is rare The area surrounding the exudate shows little inflammatory reaction and only one tonsil is involved Cervical adenopathy is usually unilateral

In contrast to streptococcal pharyngitis the onset of *diphtheria* is rarely sudden and the symptoms are not severe (see p 919) Sore throat is not a constant feature of the disease The exudate is smooth and cream colored and appears to be incorporated in the mucous membranes The membrane is removed with difficulty leaving a bleeding bed Cutaneous rashes are absent Cultures show *Corynebacterium diphtheriae*

In patients with a rash the disease must be differentiated from *German measles* and *measles* In German measles the posterior cervical lymph node enlargement is helpful as well as the fact that the rash tends to be macular and discrete The tongue never peels and a leukopenia is characteristic In measles there are prodromal respiratory symptoms and the maculopapular rash occurs chiefly on the face and neck There is no blanching of the skin following a Schultz Charlton test The presence of Koplik's spots aids in establishing the diagnosis

Streptococcal infections without exudate or a cutaneous rash must be differentiated from *influenza virus infections* and *common respiratory diseases* In general such differentiations cannot be made on clinical evidence alone so that the leukocyte count culture studies and serologic tests must be employed

Primary *herpes simplex pharyngitis* (see p 1092) and *herpangina* (see p 1091) are characterized by vesicles which rupture and produce small ulcers covered with exudate Herpetic lesions are scattered over all mucous membranes of the mouth and the kissing ulcer under the tip of the tongue is typical The ulcers of herpangina caused by Coxsackie A viruses are observed on the anterior pillars and the soft palate In both diseases the leukocyte count is usually normal

Sinusitis Otitis Media and Mastoiditis

Some degree of *sinusitis* probably occurs in every patient with streptococcal infection of the throat Aside from a purulent rhinitis which persists for a few days there are usually few symptoms or signs of involvement of the paranasal sinuses When the

the skin and to a lesser extent of the mucous membranes The onset is usually abrupt beginning after an incubation period of approximately 1 to 4 days In some patients a history of preceding respiratory infection is obtained The initial symptoms include chilliness feverishness headache malaise anorexia and vomiting The first symptom may be a true rigor At the onset the local cutaneous lesion may not be apparent although there may be slight redness in those instances where it arises in conjunction with an abrasion of the skin The skin may itch and feel sore around the point of entry of the organisms Within a few hours and usually by 24 hr the cutaneous lesion becomes obvious

The skin of the face is most commonly involved but any area of the body may be infected The point of entry around the face may be just anterior to the ear at the inner canthus of the eye around the lips and nose or over the cheeks From these points the lesion spreads rapidly reaching its maximum extent within 3 to 6 days On the face erysipelas frequently involves the butterfly area i e the cheeks and nose The lesion consists of an advancing border which is raised from the surrounding normal skin and may be purple Within this border the skin is tense and usually a dark dull red If the infection occurs in areas where the skin is lax such as around the eyes edema is pronounced The eyelids frequently become so swollen that they cannot be opened Blebs or even necrotic areas may appear as the disease progresses

At the height of the infection the temperature is usually high (104 to 105 F) although occasionally the febrile response is slight The blood stream is not uncommonly invaded during this period The disease lasts for a variable length of time but in most instances recovery is apparent by the sixth to seventh day The local lesion begins to fade in the center and is usually accompanied by some desquamation and pigmentation No scarring results unless abscesses develop

Before the introduction of chemotherapy the fatality rate was about 15 per cent During the first 6 months of life approximately 65 per cent succumb whereas in children and young adults the death rate is low In patients with fatal infections the lesion is likely to involve the trunk and in addition the blood stream is invaded

Bacteremia

Streptococci are a common cause of bacteremia but in uncomplicated tonsillitis and pharyngitis the organisms rarely invade the blood stream Bacteremia occurring under the age of twenty usually is secondary to otitis media mastoiditis or thrombosis of the lateral or cavernous sinuses In the adult invasion of the blood stream is especially likely to occur in women with puerperal infections whereas after the age of forty bacteremia is usually secondary to cellulitis and erysipelas Metastatic abscesses develop infrequently during the course of bacteremia

The diagnosis of bacteremia is difficult and can be made only by culturing the organisms from the blood The sudden development of chills and high fever either irregular or continuous suggests invasion of the blood stream Severe headache nausea vomiting and delirium are common symptoms In streptococcal bacteremia there may be arthritis signs of pneumonia petechiae or skin eruptions In fulminating cases anemia develops rapidly and jaundice may occur Without specific therapy the mortality rate is 70 per cent

Pyelonephritis

Infections of the kidney and urinary passages are discussed in detail in Chap 144 (p 967) Here it should be emphasized that streptococci usually belonging to group D may be isolated from the urine of patients with infection of the urinary tract When the organisms are present in large numbers there is usually dysuria frequency flank pain fever and pyuria

Treatment

There are now several agents which may be employed in the therapy of aerobic streptococcal infections The sulfonamides have been widely employed These compounds exert a bacteriostatic effect against all Lancefield groups except D However there are strains of group A streptococci that have acquired resistance Most antibiotic compounds exhibit a more marked effect than the sulfonamides but penicillin displays the maximal antistreptococcal activity Penicillin actually kills group A organisms and if it is administered for at least 10 days all streptococci are eliminated in most instances Therapeutic measures which do not result in the eradication of the infecting organism do not alter the attack rate of rheumatic fever

The administration of penicillin or other antibiotics within 24 hr of the onset of streptococcal respiratory infections results in a definite favorable effect on the symptoms and signs associated with the acute illness When therapy is instituted after 18 hr a favorable effect is difficult to demonstrate but suppurative complications including sinusitis otitis media and peritonsillar cellulitis are still prevented The time that treatment is started is not decisive in the reduction of rheumatic fever however early therapy may be important in the prevention of nephritis

In the average case of streptococcal infection, whether scarlet fever tonsillitis or erysipelas sufficient concentration of antibiotic can be maintained most readily by a single injection of 600 000 to

The pulse and respiratory rates are increased and cyanosis may be prominent The temperature tends to be high (104 F) and septic in type Examination reveals local signs of pneumonia with scattered fine rales and occasional areas of dullness Frank signs of lobar consolidation are rare

The leukocyte count is almost invariably elevated to 20 000 to 30 000 and the sputum is found to contain large numbers of group A organisms Usually the blood cultures are sterile when bacteremia occurs the prognosis is poor

The untreated disease runs a variable course In most instances recovery is delayed for several weeks and lung abscess and bronchiectasis are not uncommon complications In fatal cases mediastinitis and pericarditis may occur The most frequent complication is empyema which occurs in 20 per cent of the cases

Streptococcal *empyema* is usually secondary to pneumonia caused by the same organism but occasionally it arises following other infections of the lung infarcts or lung tumors It is most likely to occur under the age of thirty years and the mortality rate in untreated cases is high Early in the disease the pleural fluid may be hemorrhagic It becomes thick and purulent slowly in contrast to the exudate seen in pneumococcal empyema

Pericarditis Arthritis Peritonitis and Meningitis

Streptococcal infections of the various body cavities result from bacteremia or from extension from a local lesion *Pericarditis* a rare complication is especially likely to occur during the course of pneumonia or empyema The diagnosis is difficult since the symptoms arising from pericarditis are overshadowed by the primary disease The first sign may be a sudden increase in pulse rate and the development of an audible pericardial friction rub Roentgenograms are of great aid in establishing the diagnosis Once the diagnosis is suspected aspiration and culture of the fluid are indicated

Suppurative arthritis is secondary to bacteremia or to extension of a local cellulitis It is a rare complication of streptococcal sore throat Pain is the most common symptom and usually only one joint is involved The pain is first noticed on motion but within a short period redness swelling and tenderness develop and the pain becomes intense Aspiration reveals a fluid containing polymorphonuclear leukocytes and streptococci Nonsuppurative arthritis is seen in patients with scarlet fever during the first week of illness

Infection of the peritoneum with the hemolytic streptococcus is rare but is especially apt to be associated with such local infections as erysipelas and scarlet fever In these cases the organism belongs to Lancefield group A Symptoms develop rapidly and in addition to fever and other constitutional symptoms prostration abdominal pain and vomiting are prominent The pulse is rapid and weak The abdomen is distended tender and rigid to palpation

Streptococcal *meningitis* is usually caused by group A organisms but occasionally members of other groups may be isolated from the spinal fluid In most instances the meningitis arises by extension and invasion of the blood stream from an otitis media mastoiditis or petrositis which are especially likely to develop following infection of the respiratory tract and are most frequently seen in the young age groups Prior to the introduction of specific therapy these infections were always fatal The symptoms of streptococcal meningitis are not distinguishable from other types of bacterial meningitis It should be emphasized that all patients especially infants with infections of the middle ear should be watched for signs of meningeal irritation Once such signs develop lumbar puncture and culture of the spinal fluid establish the diagnosis

Wound and Skin Infections Lymphangitis Puerperal Fever and Erysipelas

As indicated earlier *wound and skin infections* are usually the result of contamination Children with chickenpox impetigo and other skin lesions may become infected with group A and C streptococci

Hemolytic streptococci are responsible for the majority of cases of the familiar form of *lymphangitis* The disease is characterized by the rapid development of one or more fine red streaks extending upwards from the hand or foot Usually the process continues up to the axilla or groin and the lymph nodes in these areas become enlarged and tender Associated with the spread of the infection in the lymphatics such symptoms as rigor fever malaise headache and vomiting occur Occasionally the blood stream is invaded The original site of infection in these cases of lymphangitis may be unapparent Although these infections may be serious the course of the illness is usually short and suppuration seldom occurs along the course of the lymphatics or in the regional lymph nodes

Puerperal infections caused by hemolytic streptococci are always serious Following abortion or delivery the streptococci invade the endometrium and lymphatics The infection may spread to the surrounding structures producing cellulitis phlebitis abscess peritonitis or bacteremia The patient develops a high irregular fever associated with rigors The pulse is rapid The diagnosis is based on local signs of infection as well as on such laboratory findings as leukocytosis and isolation of streptococci from the blood stream or from the cervical discharge

Erysipelas is an acute streptococcal infection of

phylaxis when given to populations already experiencing an epidemic will control the outbreak as long as the drug is administered When therapy is stopped streptococcal infections again occur because of the failure of sulfonamides to eliminate the infecting organism For this reason oral penicillin in doses of 250 000 units two or three times daily for 10 days or the injection of 1 200 000 units of benzathine penicillin are preferred forms of prophylaxis in large population groups Benzathine penicillin in doses of 600 000 and 1 200 000 units will protect the individual from new infections for from 3 and 4 to 6 weeks respectively

Tonsillectomy has been employed widely as a prophylactic measure for streptococcal infections *It is obvious that tonsillitis cannot occur if the* organ is removed but there is no protection afforded against streptococcal pharyngitis Indeed the only measurable effect is that tonsillectomy makes subsequent recognition of the cause of the respiratory illness difficult

Many attempts have been made to control respiratory disease by altering certain environmental factors by using for example ultraviolet light aerosols and various dust holding procedures and by treating bed clothing with oils It has been demonstrated that such methods decrease the contamination of the air but the degree of their effectiveness in preventing infection is slight

Several local infections of various organs require special comment Erysipelas is difficult to control In the few patients who have repeated attacks the prophylactic use of sulfonamides would be justified Wound infections and puerperal sepsis are best prevented by good surgical aseptic techniques and the avoidance of unnecessary examinations

LATE NONSUPPURATIVE COMPLICATIONS OF GROUP A STREPTOCOCCAL INFECTIONS

As indicated previously beta streptococcal infections assume importance not only because of the high morbidity and the immediate suppurative complications but also because of the late sequelae There is considerable evidence that rheumatic fever acute glomerulonephritis and scleredema adultorum (see p 1706) are precipitated by if not directly related to infection with the beta streptococcus Rheumatic fever may be followed by valvular disease and therefore this sequela of streptococcal infection assumes importance as a cause of chronic illness

Etiology and Pathogenesis

Although group A streptococci are considered to be the inciting agent of both rheumatic fever and glomerulonephritis these two diseases have never been reproduced in animals nor have the mechanisms involved been defined Therefore it is not surprising that numerous theories have been proposed to explain the nature of the cardiac and renal complications

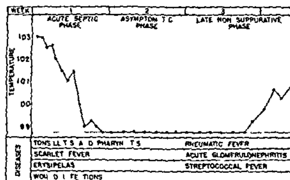

Fig 139 The various phases of hemolytic streptococcal infections

Streptococcal infections are characterized by an acute toxic or septic phase which lasts from 3 to 7 days Following the acute illness the patient seemingly recovers completely except for those few individuals who have developed a suppurative complication After a latent period (termed *phase II* by Coburn) the patient may again present symptoms and signs of illness but this time the manifestations are related to involvement of new areas of the body and the illnesses developing after the latent period present a varied clinical picture These illnesses have been collectively termed the late nonsuppurative complications of hemolytic streptococcal infections (Fig 139) The latent period and the resemblance of certain manifestations to serum sickness suggest some altered or unusual tissue reaction but to ascribe hypersensitivity as the responsible mechanism on the basis of this evidence alone is not warranted

The spectrum of the nonsuppurative illnesses is broad Certain patients develop fever with no localizing signs Others exhibit lymphadenitis with fever Such illnesses have been called streptococcal fever but it seems probable that they represent mild rheumatic attacks Approximately 3 per cent develop signs of involvement of the joints or heart and a diagnosis of rheumatic fever is evident In a few depending on the serologic type of infecting streptococcus acute glomerulonephritis becomes manifest Skin eruptions such as erythema marginatum erythema nodosum and scleredema adultorum occasionally appear

This sequence of (1) an acute streptococcal respiratory illness (2) a latent period of 1 to 5 weeks and (3) the development of nonsuppurative illness occurs with sufficient frequency to suggest a causal relationship to the group A *streptococcus* In the family unit experiencing streptococcal in

900 000 units of benzathine penicillin Another method is the intramuscular administration of 600 000 units of procaine penicillin in 2 per cent aluminum monostearate in oil every 2 or 3 days for three injections In patients who exhibit rheumatic heart disease and who develop a streptococcal infection it may be advisable to administer 600 000 units of procaine penicillin twice daily for 2 weeks

Oral therapy may be prescribed but it should be emphasized that many patients discontinue the medication when the acute phase symptoms subside Under these circumstances the organism frequently invades the tissues again and a clinical relapse occurs More important the attack rate of the nonsuppurative complications is not altered All forms of oral medication must be taken in full doses for at least 10 days and preferably for 2 weeks Oral preparations of penicillin are given in doses of 250 000 units four times daily If the patient is sensitive to penicillin then erythromycin in doses of 0 2 Gm is administered every 6 hr Tetracycline is given every 4 hr in a dose of 0 25 Gm Chlortetracycline and oxytetracycline may also be employed

The *sulfonamides* should never be employed in the treatment of streptococcal infections since they fail to eliminate the infecting organism and do not alter the subsequent attack of rheumatic fever Application of penicillin or other drugs by means of troches or sprays has little effect on the local inflammatory lesion or on the infecting organism

Penicillin appears to exert a definite effect on the suppurative complications of tonsillitis and pharyngitis Penicillin treatment of otitis media is followed by a gradual decrease in the amount of exudate redness of the drum disappears and within 4 to 14 days there is no further aural discharge The temperature if elevated returns very rapidly to normal Complications such as mastoiditis are rare during this form of therapy If treatment is instituted before aural discharge occurs the drum membranes must be watched closely A tympanic cavity filled with purulent exudate requires drainage In general it is wise to continue penicillin treatment for several days after all discharge has ceased and the temperature has returned to normal Premature discontinuance of treatment may lead to a recurrence It is perhaps important to emphasize that staphylococcal infections of the middle ear are common in patients with group A streptococcal infections of the throat and in these cases discharge is likely to be prolonged

Infections of the mastoid and paranasal sinuses should likewise be treated by the parenteral administration of penicillin Streptococcal pneumonia should be treated with somewhat larger amounts of penicillin a dose of 40 000 units every 3 hr is suggested From 30 000 to 50 000 units every 2 hr should be given to patients with puerperal sepsis and bacteremia Empyema purulent pericarditis and arthritis are best treated by local instillation of 10 000 to 50 000 units of penicillin every 48 to 72 hr until cultures are sterile In addition full doses of parenteral penicillin should be administered In these infections early treatment is required if surgical drainage is to be avoided

In patients developing localized collections of pus surgical drainage should be promptly established Surgery should not be injudiciously employed because of the danger of spread of the infectious process Patients with lymphangitis and arthritis should have the involved parts immobilized

General measures for the supportive and symptomatic therapy of infections should be employed The use of saline gargles and irrigations of the throat may be effective in the relief of the angina associated with tonsillitis The use of cold applications to erysipelas or to tender and enlarged cervical lymph nodes frequently affords symptomatic relief

Prevention

It may be stated that there is no completely adequate method for the prevention of streptococcal infections A number of procedures will limit the spread of the organism to some extent The problem is exceedingly complicated because group A streptococci occur in the upper respiratory tract of many individuals

In the past it has been customary to isolate all patients with scarlet fever but today such procedures seem unwarranted for no precautions are taken for sore throat without a rash caused by the same bacterium Any patient with a streptococcal infection of the upper respiratory tract may be a source of infection During the acute stage of all such illnesses the patient should be advised against intimate contact with others

Approximately 90 per cent of patients with streptococcal infections continue to carry the organism in the pharynx 3 months after the acute infection Usually the number of organisms is small Individuals with suppurative complications of the sinuses are likely to harbor large numbers of streptococci and would appear to be a dangerous source of infection Proper therapy of acute infections with penicillin prevents the development of the carrier state

There is no specific immunizing procedure which will protect against streptococcal infections This is not surprising since the evidence today is that immunity is largely type specific

Individuals or groups of individuals may be protected from streptococcal infections by the prophylactic use of sulfonamide drugs For this purpose 1 Gm sulfadiazine is administered daily Such pro

these nephritogenic strains is not constant suggesting that either the strains vary in their nephritogenic capacity or some other factor is operative Since the attack rate may approach 90 per cent following infection multiple cases within the family unit are common

Pathology

Rheumatic Fever

The tissue changes occurring during the course of rheumatic fever are found in the fibrous tissues located throughout the body The pathologic changes are widespread but because alterations in certain organs result in abnormal function the clinician and the pathologist have been especially interested in the changes occurring in the heart joints and brain The characteristic change evoked by acute rheumatic fever is the development of minute nodules called *Aschoff bodies* This lesion is considered specific for rheumatic fever The Aschoff nodule develops as a result of swelling and fusion of the collagenous ground substances of the connective tissues Around these areas which are usually oval or spindle shaped there may be collections of lymphocytes and occasionally polymorphonuclear leukocytes As the lesion ages fibrosis occurs leaving a minute scar

In patients dying with acute rheumatic myocarditis the heart shows few gross abnormalities The left ventricle is enlarged and there is widening of the atrioventricular valves The leaflets of the mitral valve may be slightly swollen and thickened and along the point of contact of the cusps a row of small beadlike vegetations is observed In patients with pericarditis there may be fluid in the pericardial sac and the heart may be covered with a fibrinous exudate

Microscopic examination reveals small areas of inflammation scattered throughout the myocardium These Aschoff nodules are especially prominent in the base of the interventricular septum and beneath the endocardium of the left atrium It is easy to visualize that these lesions associated with an inflammatory reaction give rise to alterations in the conductive mechanism of the heart

The endocardial lesions are most frequently found in the valves and the left atrium In the valve leaflets there is edema and subendothelial infiltration by lymphocytes and occasionally by polymorphonuclear leukocytes The endothelium is damaged and it is in these areas that fibrin is deposited producing the beadlike vegetations The chordae tendineae are also involved in this inflammatory process As the disease continues fibrosis develops with subsequent contraction of the tissues producing the valvular deformities characteristic of chronic rheumatic heart disease

The joints become red swollen and tender The periarticular tissues and synovia are edematous and show collections of mononuclear cells The synovial fluid becomes increased Involvement of the tendons especially the hamstring and Achilles tendons gives rise to the so called "growing pains" of childhood Subcutaneous nodules loosely connected to the tendon sheaths are likely to be found during the acute phase of the disease in children

In the brain true Aschoff bodies are seldom observed instead there is a perivascular collection of round cells There may be proliferation of the intima and thrombosis of vessels

Inflammatory reactions have been described in the tissues of other organs of the body In the lung there may be an interstitial pneumonia and hemorrhage

Acute Glomerulonephritis

The kidneys are normal or slightly enlarged and appear pale Over the surface small punctate hemorrhages are observed Histologically the earliest lesion is an increased cellularity of the glomerulus with infiltration with polymorphonuclear cells Red cells and leukocytes appear in Bowman s space and in the tubules The basement membrane is thickened The tubular cells may show some swelling Acute fibrinoid necrosis of the arterioles and glomerular tufts is seen Lesions observed at autopsy after several weeks or months of illness show epithelial crescents fibrinoid necrosis tubular degeneration and inflammatory infiltration around the glomerulus Fibrosis is a late manifestation The relation of these latter changes to nephritis following group A infections has not been well defined

Acute Rheumatic Fever

Clinical Manifestations One of the outstanding characteristics of the late nonsuppurative complications of streptococcal infections is the variation of the clinical features Frequently a definite diagnosis of rheumatic fever is easily made but there are also many instances where such a diagnosis is difficult if not impossible The correct diagnosis may become apparent only after a long period of observation

Streptococcal fever is a term applied when there is fever usually of mild degree without other signs of rheumatic activity or of a suppurative process A history of a preceding pharyngitis is usually obtained There may be some cervical lymphadenitis but in many instances the glands are not prominent or tender In some patients the temperature may be normal except during the late afternoon An increase in the total leukocyte count or in the sedimentation rate may accompany the fever

Rheumatic fever may be insidious in onset or it may develop rapidly Although it is common for

fections in patients with scarlet fever and in food and milk borne outbreaks it is not uncommon to observe rheumatic fever and nephritis Other non bacterial respiratory infections are not followed by these complications

Further evidence that rheumatic fever and nephritis are related to group A streptococcal infections is obtained from study of patients with these diseases Usually a history of a recent infection of the throat is obtained and cultures frequently exhibit hemolytic colonies Antistreptolysin titers of the serum are elevated Measures known to protect the individual from streptococcal infections reduce the incidence of rheumatic fever and nephritis

The exact mechanism whereby rheumatic fever and acute glomerulonephritis are produced is not known The majority of students favor some form of hypersensitivity mechanism but it is now apparent that the substances responsible for the tissue reactions are not identical in nephritis and rheumatic fever Furthermore the host response to infection with the streptococcus in patients with nephritis is different from that in patients with rheumatic fever in the first instance a recurrence is rare in the second it is common In nephritis the observation that hematuria is observed during the acute streptococcal illness suggests the direct action of some nephritotoxic substance however the hematuria clears and subsequently becomes apparent again In rheumatic fever and to a less extent in nephritis the patient responds to the initiating infection by the production of large amounts of antibody to various streptococcal antigens Why such a response is more likely to be associated with a nonsuppurative complication is unknown but *this observation contributes to the interest in the* antigen antibody reaction in relation to the mechanisms involved in tissue damage

In experimental models tissue reactions in the kidneys and to a less extent in the heart have been produced by a variety of procedures These observations have contributed to the emphasis on altered reactivity of the tissues but it is difficult to translate these studies to the diseases nephritis and rheumatic fever as they occur in man Indeed in cases of rheumatic valvular heart disease there is some evidence indicating that the streptococcus produces its damage directly Green and others have recovered hemolytic streptococci from the valves of patients dying with acute rheumatic fever

Epidemiology of Rheumatic Fever and Nephritis

There are no reliable figures of the incidence of rheumatic fever and glomerulonephritis because the diseases are not reportable and in many instances their manifestations are so mild that the illnesses are not recognized That rheumatic fever occurs frequently is indicated from reports which show that approximately 2 to 3 per cent of patients with streptococcal infections subsequently develop rheumatic fever Since most people experience one to several streptococcal infections in a lifetime it can be assumed that rheumatic fever is common but frequently goes unrecognized More accurate information is available from studies of heart disease 1 to 6 per cent of the population exhibit specific valvular defects Since many patients with rheumatic fever recover completely such high rates of valvular defects must represent many cases of rheumatic fever in the population In contrast to rheumatic fever attack rates for nephritis following streptococcal infections vary from 0 to 90 per cent. Determination of the number of cases of chronic nephritis gives no indication of the past experience of the population with the acute disease or with streptococcal infections since the relationship of the chronic disease to the streptococcal infection is not clear

Rheumatic fever occurs with equal frequency in the two sexes whereas clinical manifestations of nephritis are observed more frequently in the male Both complications occur primarily between the ages of two and thirty with a peak of incidence at seven Nephritis is somewhat more frequently observed in the young infant than rheumatic fever Acute rheumatic fever in the adult is likely to be a recurrence rather than an initial attack Age does not alter susceptibility to rheumatic fever but streptococcal infections are less likely to be acquired in adult life

Individuals who have experienced one attack of rheumatic fever are especially susceptible to subsequent attacks It has been estimated that as many *as 40 per cent of patients will experience a recur*rence within 1 year after the initial attack However as time progresses the risk of recurrence decreases

Wilson has stated that the attack rate of rheumatic fever in siblings of rheumatic parents is higher than in siblings of parents free of the disease but recent data show that following a streptococcal infection the attack rate is 3 per cent irrespective of the presence or absence of the rheumatic state in the parents These results would indicate that there is no increased susceptibility to rheumatic fever in such families

The other epidemiologic features of acute rheumatic fever and acute nephritis are those of streptococcal infections in general In addition the epidemiology of nephritis is governed by the fact that not all strains of group A streptococci are capable of producing renal disease The evidence at present indicates that strains belonging to type 12 account for the majority of cases throughout the world In addition strains of type 4 25 and a newly recognized type termed *Red Lake* may produce nephritis The attack rate of nephritis following infection with

One of the most characteristic features of rheumatic fever is the development of *subcutaneous nodules* These nodules which vary in size from 1 mm to 2 cm are especially likely to develop over the extensor tendons of the hands and feet over the extensor aspects of the knee and elbow and over the spine scapulas and skull Usually they are distributed symmetrically and may occur in crops They lie deep in the tissue and the skin is movable over their surfaces They are not painful Detection of these nodules is best accomplished by inspection of the skin when drawn taut by flexion of the joints The nodules persist for a few days to several weeks but always disappear Since subcutaneous nodules are especially likely to develop in patients with severe carditis they are seldom helpful from the standpoint of diagnosis

The tendency toward *recurrent attacks* is a striking feature of rheumatic fever Approximately three fourths of all patients with recognizable rheumatic fever will develop a recurrence of the disease so that a previous history of an attack aids in the establishment of the proper diagnosis

Numerous symptoms physical signs and abnormalities in laboratory examinations aid in the establishment of proper diagnosis *Fever* is usually associated with acute rheumatic fever although it may be absent in patients with chorea Fever may be the only clinical manifestation of the disease other studies such as serial electrocardiograms and detection of endocardial murmurs being required to establish the diagnosis A diagnosis of rheumatic fever made solely on the basis of low grade fever is not warranted but it should be emphasized that fever may be the only sign of rheumatic activity

Little experience is required to appreciate the protean character of rheumatic fever Studies of outbreaks of streptococcal infection emphasize that nonsuppurative sequelae include typical rheumatic fever and a low grade often continuous fever without signs of rheumatic activity It is natural to assume that such cases of so called streptococcal fever are produced by the same mechanism responsible for the clinically recognizable form of rheumatic fever A history of a preceding streptococcal infection is of help in diagnosis (Fig 140)

During the acute phase of rheumatic fever various *rashes* may appear Most typical is *erythema marginatum* This rash is said to occur in 15 per cent of patients with acute rheumatic fever and probably should be considered indicative of active rheumatic infection It is characterized by a depressed center and an erythematous margin which may form rings When the lesions fuse various gyrate patterns are observed The rash is evanescent and may become apparent only by warming the body Other rashes include erythema nodosum urticaria and various purpuric lesions

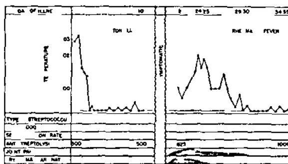

Fig 140 The time sequence of streptococcal tonsillitis and rheumatic fever

Abdominal pain occurs frequently and may be incorrectly diagnosed as resulting from acute appendicitis Since a leukocytosis occurs in both rheumatic fever and appendicitis operation is frequently performed Careful search for other signs of rheumatic activity should be made in all children and young adults complaining of abdominal pain and fever

Not only does abdominal pain occur as a manifestation of acute rheumatic fever but also pleuritic pain is observed *Pleurisy* is usually associated with severe rheumatic fever and gives rise to pain on respiration Rarely it is the initial manifestation of the illness Usually the pleurisy does not persist for more than a few days and symptoms may be relieved as fluid accumulates in the intrapleural space In some patients and again especially in those with a severe illness symptoms and signs of *pneumonia* may develop The sputum may become blood streaked Physical signs are frequently difficult to interpret for there is usually concomitant myocarditis and cardiac failure Roentgenographic examination of the lungs is a most valuable procedure in patients suspected of having pneumonia

Epistaxis is commonly observed in patients with acute rheumatic fever The exact cause of these recurrent attacks of bleeding is not known Hypoprothrombinemia may be due to salicylate administration

Laboratory Findings The urine is usually normal Traces of albumin may occur during the febrile period and microscopic hematuria is observed on occasion In patients with severe or prolonged infections various degrees of anemia are common A leukocyte count of from 15 000 to 30 000 is *the rule* during the acute phases of infection but in some patients the count may be normal

The sedimentation rate is an excellent index of rheumatic activity and is generally considered more reliable than the leukocyte count The rate of *sedimentation* of the cells almost invariably increases during the acute phases of the infection *with clin*

ients to give a history of a preceding strepto ocal respiratory infection followed by a latent riod of from several days to 6 weeks occasionally nptoms of rheumatic fever develop without a ent symptom free period Usually the patient nplains of *malaise which is soon followed by fev* ishness perspiration prostration and polyar itis

In the absence of a specific diagnostic test the ognition of rheumatic fever depends upon the esence of a combination of symptoms and signs which the most important are polyarthritis car is chorea subcutaneous nodules erythema mar iatum fever and dramatic improvement of pain d fever following the administration of salicylates is important to stress that many of these mani tations may be absent in a given instance

Although *migratory polyarthritis* is considered e of the typical symptoms of rheumatic fever it also a confusing symptom since arthralgia may caused by other diseases In rheumatic fever inful joints develop rapidly and the ankles knees ps shoulders elbows and wrists are likely to be olved Occasionally the small joints become in med Several joints may become involved simul ieously or they may be affected in rapid succes n As one joint becomes involved the pain and elling in another may be receding Arthralgia in y one joint may last from a few hours to several ys or rarely weeks Commonly there are all the ;ns of acute inflammation with redness swelling at pain and tenderness

In children arthritis may be atypical the mani itations being pain and tenderness without elling of the joint The arthritis of rheumatic er does not suppurate and normal function is itored following subsidence of symptoms and ;ns of inflammation

Death during the course of acute rheumatic fever due to active *carditis* Patients with severe cardiac volvement appear prostrated and pale the fever apt to be high the pulse is rapid and weak and ere may be associated symptoms and signs of ilure of the heart A few patients complain of ecordial discomfort and more rarely of severe un The diagnosis of active carditis is established most patients only after careful examination in uding the use of the electrocardiogram

The single sign indicative of involvement of the idocardium is a murmur The most common mur ur associated with the initial attack is the mitral stolic which in some patients is associated with soft aortic diastolic murmur The mitral systolic urmur may be functional in origin Those mur urs which vary little with respiration persist in irious body positions with maximum intensity at ie apex are high pitched occur throughout most f systole and persist during the period of observation should be considered indicative of endocarditis The faint systolic murmur localized to the apex which is heard only while the heart rate is rapid is usually functional in origin Unimportant murmurs frequently disappear as the patient im *proves During the phase of acute carditis* a mid diastolic rumble may be heard at the apex In patients with preceding rheumatic infections a mitral diastolic or presystolic murmur indicates rheumatic heart disease

Cardiac enlargement is frequently encountered in children but seldom observed in the adult The diagnosis of involvement of the myocardium is usually based on the recognition of disturbances of rhythm and electrocardiographic abnormalities Most patients with rheumatic fever if examined frequently will show evidence of myocardial in volvement Tachycardia is frequent Gallop rhythm usually heard during the acute phases of the ill ness is especially apt to occur The heart sounds may be muffled or the first sound may vary in intensity The finding of dropped beats suggests a partial heart block (Wenckebach phenomenon) Auricular fibrillation uncommon in children may be associated with recurrent attacks of rheumatic fever in the adult

The electrocardiographic change most frequently encountered during the course of acute rheumatic fever is prolongation in the P R interval This inter val usually becomes normal as signs of infection disappear but prolongation may persist Other ab normalities include partial auriculoventricular heart block auriculoventricular dissociation inversion of T waves and bundle branch block

Discomfort over the precordial area does not always indicate acute pericarditis but the detection of a harsh to and fro friction rub is pathognomonic Frequently the precordial pain is severe in pa tients exhibiting a friction rub Rheumatic peri carditis in children is often associated with little pain Effusion into the pericardial sac may develop and must be differentiated from cardiac dilatation

One of the major manifestations of rheumatic fever is *chorea* or St Vitus dance In children it is observed in approximately one half the patients whereas in adults it is rare Commonly chorea ap pears late in the illness so that it may be the only manifestation of the rheumatic state Chorea usually develops slowly so that a week or two is required before the parents realize the child is ill Typically the patient is restless nervous and emotionally un stable and performs many purposeless movements The manifestations of chorea are usually mild and careful observation is required to detect the in coordination Hyperextension of the fingers grimac ing and purposeless movements of the tongue ex tremities and fingers are characteristic (see p 249)

One of the most characteristic features of rheumatic fever is the development of *subcutaneous nodules* These nodules which vary in size from 1 mm to 2 cm are especially likely to develop over the extensor tendons of the hands and feet over the extensor aspects of the knee and elbow and over the spine scapulas and skull Usually they are distributed symmetrically and may occur in crops They lie deep in the tissue and the skin is movable over their surfaces They are not painful Detection of these nodules is best accomplished by inspection of the skin when drawn taut by flexion of the joints The nodules persist for a few days to several weeks but always disappear Since subcutaneous nodules are especially likely to develop in patients with severe carditis they are seldom helpful from the standpoint of diagnosis

The tendency toward *recurrent attacks* is a striking feature of rheumatic fever Approximately three fourths of all patients with recognizable rheumatic fever will develop a recurrence of the disease so that a previous history of an attack aids in the establishment of the proper diagnosis

Numerous symptoms physical signs and abnormalities in laboratory examinations aid in the establishment of proper diagnosis *Fever* is usually associated with acute rheumatic fever although it may be absent in patients with chorea Fever may be the only clinical manifestation of the disease other studies such as serial electrocardiograms and detection of endocardial murmurs being required to establish the diagnosis A diagnosis of rheumatic fever made solely on the basis of low grade fever is not warranted but it should be emphasized that fever may be the only sign of rheumatic activity

Little experience is required to appreciate the protean character of rheumatic fever Studies of outbreaks of streptococcal infection emphasize that nonsuppurative sequelae include typical rheumatic fever and a low grade often continuous fever without signs of rheumatic activity It is natural to assume that such cases of so called streptococcal fever are produced by the same mechanism responsible for the clinically recognizable form of rheumatic fever A history of a preceding streptococcal infection is of help in diagnosis (Fig 140)

During the acute phase of rheumatic fever various *rashes* may appear Most typical is *erythema marginatum* This rash is said to occur in 15 per cent of patients with acute rheumatic fever and probably should be considered indicative of active rheumatic infection It is characterized by a depressed center and an erythematous margin which may form rings When the lesions fuse various gyrate patterns are observed The rash is evanescent and may become apparent only by warming the body Other rashes include erythema nodosum urticaria and various purpuric lesions

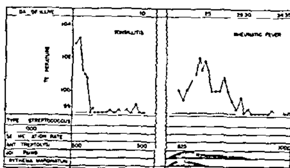

Fig 140 The time sequence of streptococcal tonsillitis and rheumatic fever

Abdominal pain occurs frequently and may be incorrectly diagnosed as resulting from acute appendicitis Since a leukocytosis occurs in both rheumatic fever and appendicitis operation is frequently performed Careful search for other signs of rheumatic activity should be made in all children and young adults complaining of abdominal pain and fever

Not only does abdominal pain occur as a manifestation of acute rheumatic fever but also pleuritic pain is observed *Pleurisy* is usually associated with severe rheumatic fever and gives rise to pain on respiration Rarely it is the initial manifestation of the illness Usually the pleurisy does not persist for more than a few days and symptoms may be relieved as fluid accumulates in the intrapleural space In some patients and again especially in those with a severe illness symptoms and signs of *pneumonia* may develop The sputum may become blood streaked Physical signs are frequently difficult to interpret for there is usually concomitant myocarditis and cardiac failure Roentgenographic examination of the lungs is a most valuable procedure in patients suspected of having pneumonia

Epistaxis is commonly observed in patients with acute rheumatic fever The exact cause of these recurrent attacks of bleeding is not known Hypoprothrombinemia may be due to salicylate administration

Laboratory Findings The urine is usually normal Traces of albumin may occur during the febrile period and microscopic hematuria is observed on occasion In patients with severe or prolonged infections various degrees of anemia are common A leukocyte count of from 15 000 to 30 000 is the rule during the acute phases of infection but in some patients the count may be normal

The sedimentation rate is an excellent index of rheumatic activity and is generally considered more reliable than the leukocyte count The rate of sedimentation of the cells almost invariably increases during the acute phases of the infection with clin

ical improvement the rate decreases and returns to normal. In patients with carditis and cardiac failure normal values may be obtained, but as failure disappears the sedimentation of the cells increases.

The determination of C reactive protein content of the blood is a useful procedure in judging rheumatic activity. Since this protein also appears in the blood during the course of acute bacterial infections, the reaction must not be considered specific. Culture of the tonsils and oropharynx may show beta streptococci of Lancefield group A, but failure to isolate these organisms even early in the course of the disease is not unusual. Of significance is the finding of a high antistreptolysin titer which falls during the convalescent period. Antistreptolysin titers of 200 or more indicate a recent infection by group A streptococci; they are not diagnostic of rheumatic fever. Early in the course of rheumatic fever titers of less than 100 are rare.

Diagnosis. There is no laboratory test available that establishes the diagnosis of acute rheumatic fever. *Polyarthritis, carditis, chorea, subcutaneous nodules, erythema marginatum* and *recurrent attacks* characterize the disease. According to Jones the diagnosis of rheumatic fever becomes established when two or more of the above manifestations coexist. It should be emphasized that rheumatic fever undoubtedly occurs in the absence of these conditions, but only by long observation is it usually possible to make certain of the diagnosis.

Rheumatic fever must be differentiated from other forms of acute arthritis. Under the age of twenty *gonococcal arthritis* may be confused with rheumatic fever (see p 875).

Rheumatoid arthritis, although relatively rare in children, is generally polyarticular in its manifestations, so that it is commonly confused with acute rheumatic fever (see p 1718). Temporomandibular joint involvement is rare in rheumatic fever and common in rheumatoid arthritis. The development of deformities or ankylosis clearly indicates rheumatoid arthritis.

Septic or *purulent arthritis* is recognized readily in most instances, and cultures of the blood and joint fluid establish the correct diagnosis. *Tuberculous arthritis* is usually monoarticular in distribution and subacute in its course. Some cases of acute *disseminated lupus erythematosus* may be difficult to distinguish from acute rheumatic fever. The former disease almost invariably occurs in females and is associated with leukopenia, hematuria and in most instances a rash over the face (see p 1700).

In the adult, and especially in the male, *gout* must be considered. The occurrence of tophi, podagra and an increased uric acid content of the blood, as well as the appearance of erosions of the bone in the roentgenograms, serve to differentiate gout from rheumatic fever.

The administration of salicylic acid compounds is often helpful in differential diagnosis. In rheumatic fever these drugs produce rather marked symptomatic relief; the temperature decreases and the pulse slows.

In patients with fever and valvular heart disease *subacute bacterial endocarditis* may mimic rheumatic fever. Here the presence of petechiae, enlarged spleen, hematuria or a positive culture of the blood assist in establishing the diagnosis.

Course and Prognosis. Approximately 4 per cent of hospitalized patients die during their initial attack of rheumatic fever, and in every instance death is due to active carditis. The course of the acute illness is extremely variable and prognosis should be guarded. In a few patients a normal status is apparent within 1 week, but the majority require 4 to 6 weeks before the clinical and laboratory signs of activity disappear. In the past there was an appreciable number of patients who continued to exhibit signs of rheumatic fever, either progressive or cyclic in nature. Today such a course is rarely observed, presumably because of better therapy rather than because of a fundamental change in the character of the rheumatic process.

The most important feature of rheumatic fever is carditis. If the patient is going to manifest disease of the heart, signs are readily detected early in the acute illness. Patients who subsequently develop chronic valvular heart disease usually exhibit murmurs during the acute illness. Although there is some correlation between the severity of acute carditis and chronic valvular deformities, it is difficult to make a prognosis until the patient has been observed for many months. The occurrence of repeated attacks of rheumatic fever alters the prognosis considerably. Repeated attacks usually result in serious cardiac injury.

Although death in the child is usually due to active carditis, in the adult mechanical failure of the heart results from marked valvular deformities. The adult patient succumbs to heart failure with auricular fibrillation, embolic episodes or bacterial endocarditis. The latter complication develops most frequently in patients who do not exhibit signs of failure during the acute illness. In all patients showing signs of cardiac failure active rheumatic fever should be suspected.

Treatment. During an attack of acute rheumatic fever attention is directed toward providing nursing care, a good diet, adequate fluid intake and rest in bed. Most physicians believe that *bed rest* is an important feature of treatment, and it undoubtedly is in patients with severe carditis. Absolute bed rest is difficult to maintain during therapy because the drugs employed relieve all symptoms in the majority of instances. It is common practice to require bed rest until clinical signs of activity have

disappeared The pulse rate leukocyte count sedimentation rate and C reactive protein are employed as an index of activity of the disease Some restriction of physical exertion is advised until these indices return to normal values

Patients with severe arthritis or substernal pain may require codeine or morphine for immediate relief The development of cardiac failure is an indication for digitalis therapy although occasionally such treatment is not followed by rapid improvement

Chorea requires special attention The patient should be placed in bed in a quiet room Precautions must be instituted so that the patient does not injure himself Feeding if difficult requires an understanding nurse Sedation usually phenobarbital should be administered in sufficient quantities to supply required rest

Once the diagnosis of rheumatic fever is established all patients should receive a course of penicillin therapy in amounts necessary to eliminate the group A streptococcus Penicillin is not withheld in patients whose oropharyngeal cultures are negative since studies have shown that the streptococci may be in inaccessible areas At present 500 000 units of penicillin is administered intramuscularly every 4 hours for 2 weeks This is followed by a single injection of 1 200 000 units of benzathine penicillin An alternative method is the injection of 600 000 units of procaine penicillin twice daily for 2 weeks to be followed by an injection of benzathine penicillin

Symptomatic therapy of acute rheumatic fever is accomplished by the use of salicylates or one of the adrenal steroid hormones All these compounds exert a favorable effect on the arthritis and the constitutional symptoms but only cortisone and hydrocortisone have been shown to alter the evolution of valvular heart disease It must be emphasized that the effect of cortisone on carditis is not marked but if therapy is instituted very early in the course of the disease a favorable effect can be demonstrated If the illness is of over 2 weeks duration at the time treatment is instituted the value of hormone therapy is doubtful Considerable more data are required before final evaluation of the role of the hormones in treatment of rheumatic fever can be determined

Sodium salicylate or acetylsalicylic acid rapidly relieves such symptoms as joint pain tachycardia and anorexia Unfortunately symptoms of salicylism appear early so that careful adjustments are necessary to obtain maximum relief of symptoms Small doses of these compounds given at frequent intervals are preferable to large doses In the adult 8 to 10 Gm during a 24 hr period may be required for maximal effect Enteric coated pills may be employed when there is intolerance Aminopyrine has been substituted for salicylates but because of its tendency to produce agranulocytosis it is not widely employed If used doses of 0 5 Gm may be given every 4 hr The leukocyte count should be followed in all patients receiving this drug

Hormone therapy is advised for all patients whose illness is of less than 2 weeks duration Corticotropin cortisone hydrocortisone and prednisone have been employed but most experience has been reported with cortisone and hydrocortisone Hydrocortisone is given in divided doses of 300 to 600 mg daily The dose is gradually reduced unless signs of activity are manifest Treatment is continued in general until there is no further improvement of the cardiac murmurs The usual course of treatment is 4 to 8 weeks After the drug is discontinued signs of activity may recur the so called "rebound phenomenon" If the rebound is not accompanied by severe symptoms it is not necessary to resume therapy Prednisone may be substituted for cortisone and has the advantage that it entails less risk of fluid retention

In all patients with active rheumatic fever and especially those receiving hormone therapy continuous prophylactic administration of sulfadiazine or penicillin should be instituted immediately after the first 2 weeks of therapy The physician should be careful in the management of each patient to make certain that a psychologically crippled individual is not produced Likewise the importance of continuous observation and prevention of recurrences should be stressed

Acute Glomerulonephritis

Most of the knowledge of acute glomerulonephritis has accumulated from study of hospitalized patients and of necessity has been derived only from individuals with symptoms Observation of patients infected with nephritogenic streptococci reveals that the spectrum of nephritis is broad many individuals exhibit signs of the disease without associated symptoms Since relatively few patients have been observed from the streptococcal infection throughout life knowledge concerning the evolution of the renal lesion is limited With the introduction of needle biopsy of the kidney the relationship of chronic nephritis to acute nephritis can be expected to be clarified in the future

The symptoms and signs of acute nephritis can be produced by a number of stimuli in addition to infection by nephritogenic streptococci Pneumococcal and other bacterial infections may be associated with hematuria and albuminuria with or without edema and hypertension Some of these illnesses are undoubtedly acute exacerbations of chronic nephritis whereas others may have resulted from infection with group A streptococci but the techniques for isolating the organism were not ade

quate In addition signs of nephritis may be produced by bee stings chemical poisons and bacteremia However most acute glomerulonephritis is caused by a few serologic types of group A streptococci

Clinical Manifestations An acute respiratory illness is an integral feature of acute glomerulonephritis Approximately 80 per cent of patients infected with group A streptococci experience clinical manifestations Since such infections are not always associated with a recognizable illness it is not surprising that a few patients exhibit no symptoms In addition in children the symptoms referable to the respiratory system may be overshadowed by infection of the skin Eczema or small abrasions may become infected by nephritogenic streptococci and may dominate the initial clinical picture presented by the patient In such instances bacteriologic studies of the oropharynx usually reveal group A streptococci

Symptoms of nephritis may develop during the acute respiratory illness but commonly they develop 10 days later Thus the symptoms of the acute respiratory illness subside or disappear completely prior to the onset of the nonsuppurative complication Occasionally the latent period may be as long as 4 weeks

As already stated most knowledge of acute glomerulonephritis is derived from the study of hospitalized patients In this population the manifestations are of such a nature that they are considered to be serious by the patient as well as by the physician Actually nephritis frequently produces few or no symptoms the only sign being an increased excretion of red blood cells Symptoms if present include vague lumbar soreness transient pain in the groins or abdomen anorexia and general malaise

In patients seeking medical care because of the development of nonsuppurative disease of the kidney *the symptoms include puffiness of the eyes* gross hematuria and headache Less commonly the initial symptom may be pain in the lumbar area severe pain in the groin or deep in the abdomen convulsions pulmonary edema and coma Any combination of the above symptoms may be associated with anorexia vomiting oliguria or anuria and nitrogen retention

Edema is one of the most common manifestations of acute nephritis Characteristically the parents observe that the face is swollen especially around the eyes The edema is most apparent upon arising in the morning Edema fluid frequently becomes manifest in the lower extremities over the sacrum or in the body cavities The exact mechanism involved in production of edema in acute nephritis is unknown but presumably it is due to sodium retention Other factors which may play a role are capillary damage and congestive heart failure Since the edema fluid exhibits a low protein content it is difficult to explain the accumulation of fluid by capillary damage

Some degree of *hematuria* is observed in all patients and the diagnosis of nephritis should not be made in its absence Individuals infected with group A streptococci exhibit an increased number of red cells in the urine during the febrile period If the organism is nephritogenic the "febrile hematuria" is even more marked 20 per cent may show over 20 cells per cubic millimeter in the uncentrifuged specimen This initial hematuria disappears only to recur in a few days in those patients who develop acute glomerulonephritis There is some evidence that "febrile hematuria" is especially likely to occur in patients who subsequently develop nephritis

Gross hematuria especially when it occurs in the male may be the presenting symptom Somewhat less than half the patients observe brown urine which lasts only a few days Since the blood must travel a long distance through the nephrons the color of the urine differs from that observed in hemorrhage from the bladder The red cells have been exposed to an acid environment which produces the brown or coffee grounds appearance Microscopic hematuria may persist for weeks and occasionally for months There is poor correlation between the severity of nephritis and the degree of hematuria

One of the characteristic signs of acute nephritis is *hypertension* The blood pressure tends to be extremely labile especially during the initial phase of the disease Patients with a normal pressure have been observed to develop marked hypertension edema cardiac dilatation and signs of failure immediately following stimuli such as an alcohol sponge bath administered as treatment for fever Observations such as this suggest that arteriolar *spasm is responsible for elevated pressures* Hypertension if it develops is likely to become manifest within a week or so of onset

Convulsions visual disturbances and coma appear to be related to the general vascular instability Sudden elevation of pressure is associated with severe headache nausea vomiting and rarely results in actual rupture of a cerebral vessel Generalized convulsions which occur mainly in young children may be the first or major symptom Blurring of vision or even amaurosis may be experienced Examination shows papilledema rarely hemorrhages into the retina and constriction of the arteries

The patient who develops hypertension is especially susceptible to vascular congestion The symptoms of congestive failure may develop rapidly *reaching a critical stage within a few hours Death*

in the early phase of the disease is commonly due to congestive failure The symptoms vary considerably from moderate dyspnea to frank signs of pulmonary edema and acute congestion with enlargement of the liver rapidly accumulating edema and elevated venous pressure

Laboratory Findings The function of the kidney is altered in many patients but specific data are meager concerning function in the patient without edema or hypertension and in the very early stages of poststreptococcal nephritis The ability to excrete water may be normal or impaired In the initial phases the ability to concentrate is usually maintained During convalescence the specific gravity may remain relatively fixed near 1 010 for several weeks or months The urea clearance may be depressed and the excretion of phenolsulfonphthalein decreased The discrete measurements show that the glomerular filtration rate is reduced in most cases renal plasma flow is normal or slightly depressed and there is a low filtration fraction There is evidence of some dysfunction of the tubular cells In patients with small urinary volumes and edema there may be azotemia

As stated under Clinical Manifestations *hematuria* of varying degrees is a constant finding in acute glomerulonephritis Microscopic examination shows red cells of normal size but in addition there are many small distorted erythrocytes and red cell stroma Identification of the distorted cells and stroma can best be accomplished in a fresh uncentrifuged specimen Bleeding from other areas of the urinary tract is not associated with abnormal cells or stroma For the proper interpretation of hematuria as well as for the long term management of the patient quantitative measurements of red cell excretion are required In the past these values have been expressed on the basis of 24 hr excretions by the method of Addis A much simpler technique is the enumeration of cells in the hemocytometer employing a fresh morning specimen which has not been stored in the icebox The cells are not sedimented prior to counting since this procedure ruptures many abnormal cells and makes the cell membranes stick together in a homogeneous mass Normal individuals excrete less than 10 red cells per cubic millimeter Patients with acute nephritis usually excrete over 100 cells although in very mild attacks or during the convalescent stages the number of cells may vary between 10 and 100 Normal individuals especially females will occasionally exhibit counts between 10 and 100 but subsequent examinations will show normal counts Some increase in cells occurs in urine containing sperm and such urine should not be considered abnormal Likewise during acute infections heart failure and infections of the urinary tract an increased number of cells is observed The presence of bacteria leukocytes and epithelial cells should be recorded The number of leukocytes is usually increased in acute nephritis If abnormal numbers of erythrocytes are observed an aliquot of urine is centrifuged and the sediment examined for casts The presence of red cell casts indicates bleeding from the glomerulus

Proteinuria is common and is always present in patients exhibiting edema or hypertension In contrast to common belief protein may be absent or present in very small quantities in patients without hypertension or edema In patients exhibiting marked degrees of proteinuria without signs of edema the illness most likely represents an acute exacerbation of chronic nephritis or some other form of renal disease

In each patient a careful search for evidence of a streptococcal infection should be made Several cultures of the throat should be obtained before institution of chemotherapy The culture is inoculated on the surface and subsurface of sheep blood agar since nephritogenic organisms frequently fail to produce typical hemolytic zones by other techniques Specimens from all members of the immediate family and other household contacts should be cultured to obtain evidence of infection in this group Those with positive cultures should be followed for urinary abnormalities Blood for antistreptolysin determinations should be taken especially in those who exhibit a negative throat culture A very high titer or a rising titer indicates a recent streptococcal infection

In acute nephritis during the active phase of the disease the sedimentation rate is increased and there may be anemia The total serum protein may be depressed slightly

Diagnosis The patient who develops hematuria edema and transient hypertension following a respiratory illness characterized by soreness on swallowing presents no difficulty in diagnosis Since hematuria is a necessary component of acute streptococcal glomerulonephritis it is necessary to consider other causes of bloody urine Bleeding from kidney or bladder tumors calculi or trauma is usually bright red and is not associated with edema or hypertension History roentgenograms of the urinary tract and microscopic examination of the urine are sufficient to establish these diagnoses Hematuria is also observed in patients with lupus erythematosis periarteritis nodosa endocarditis and bacteremia but here again other features of the history and presenting physical signs serve to differentiate the disease from diffuse glomerulonephritis

Bacterial infections of the urinary tract including tuberculosis commonly cause some hematuria but bacteriologic studies and the presence of large numbers of leukocytes indicate the correct diagnosis

quate In addition signs of nephritis may be produced by bee stings chemical poisons and bacteremia However most acute glomerulonephritis is caused by a few serologic types of group A streptococci

Clinical Manifestations An acute respiratory illness is an integral feature of acute glomerulonephritis Approximately 80 per cent of patients infected with group A streptococci experience clinical manifestations Since such infections are not always associated with a recognizable illness it is not surprising that a few patients exhibit no symptoms In addition in children the symptoms referable to the respiratory system may be overshadowed by infection of the skin Eczema or small abrasions may become infected by nephritogenic streptococci and may dominate the initial clinical picture presented by the patient In such instances bacteriologic studies of the oropharynx usually reveal group A streptococci

Symptoms of nephritis may develop during the acute respiratory illness but commonly they develop 10 days later Thus the symptoms of the acute respiratory illness subside or disappear completely prior to the onset of the nonsuppurative complication Occasionally the latent period may be as long as 4 weeks

As already stated most knowledge of acute glomerulonephritis is derived from the study of hospitalized patients In this population the manifestations are of such a nature that they are considered to be serious by the patient as well as by the physician Actually nephritis frequently produces few or no symptoms the only sign being an increased excretion of red blood cells Symptoms if present include vague lumbar soreness transient pain in the groins or abdomen anorexia and general malaise

In patients seeking medical care because of the development of nonsuppurative disease of the kidney the symptoms include puffiness of the eyes gross hematuria and headache Less commonly the initial symptom may be pain in the lumbar area severe pain in the groin or deep in the abdomen convulsions pulmonary edema and coma Any combination of the above symptoms may be associated with anorexia vomiting oliguria or anuria and nitrogen retention

Edema is one of the most common manifestations of acute nephritis Characteristically the parents observe that the face is swollen, especially around the eyes The edema is most apparent upon arising in the morning Edema fluid frequently becomes manifest in the lower extremities over the sacrum or in the body cavities The exact mechanism involved in production of edema in acute nephritis is unknown but presumably it is due to sodium retention Other factors which may play a role are capillary damage and congestive heart failure Since the edema fluid exhibits a low protein content it is difficult to explain the accumulation of fluid by capillary damage

Some degree of *hematuria* is observed in all patients and the diagnosis of nephritis should not be made in its absence Individuals infected with group A streptococci exhibit an increased number of red cells in the urine during the febrile period If the organism is nephritogenic the "febrile hematuria is even more marked 20 per cent may show over 20 cells per cubic millimeter in the uncentrifuged specimen This initial hematuria disappears only to recur in a few days in those patients who develop acute glomerulonephritis There is some evidence that febrile hematuria is especially likely to occur in patients who subsequently develop nephritis

Gross hematuria especially when it occurs in the male may be the presenting symptom Somewhat less than half the patients observe brown urine which lasts only a few days Since the blood must travel a long distance through the nephrons the color of the urine differs from that observed in hemorrhage from the bladder The red cells have been exposed to an acid environment which produces the brown or coffee grounds appearance Microscopic hematuria may persist for weeks and occasionally for months There is poor correlation between the severity of nephritis and the degree of hematuria

One of the characteristic signs of acute nephritis is *hypertension* The blood pressure tends to be extremely labile especially during the initial phase of the disease Patients with a normal pressure have been observed to develop marked hypertension edema cardiac dilatation and signs of failure immediately following stimuli such as an alcohol sponge bath administered as treatment for fever Observations such as this suggest that arteriolar spasm is responsible for elevated pressures Hypertension if it develops is likely to become manifest within a week or so of onset

Convulsions visual disturbances and coma appear to be related to the general vascular instability Sudden elevation of pressure is associated with severe headache nausea vomiting and rarely results in actual rupture of a cerebral vessel Generalized convulsions which occur mainly in young children may be the first or major symptom Blurring of vision or even amaurosis may be experienced Examination shows papilledema rarely hemorrhages into the retina and constriction of the arteries

The patient who develops hypertension is especially susceptible to vascular congestion The symptoms of congestive failure may develop rapidly reaching a critical stage within a few hours Death

During the first 2 weeks of illness and especially in patients exhibiting edema hypertension or oliguria the nutrition fluid and electrolyte intake should be carefully controlled The value of a low protein diet has not been established in man but in experimental nephritis in rats a high protein diet produces an adverse effect Another reason to limit the protein is the high potassium content Fluid should never be forced and should be limited in patients showing edema or hypertension Potassium intake should also be limited

In the treatment of *circulatory congestion* digitalis is of little value Diuretics are seldom employed but phlebotomy of 400 ml may prove beneficial

Hypertension and convulsions are difficult to control As mentioned above bed rest and limitation of sodium intake are important preventive measures In severe hypertension protoveratrine is administered in doses of 0 25 mg every 6 hr If convulsions are frequent 250 ml of a 2 per cent solution of magnesium sulfate is administered intravenously

Prevention of Rheumatic Fever and Nephritis

Both initial and recurrent attacks of rheumatic fever and nephritis can be prevented Prompt and adequate treatment of group A streptococcal infections will prevent both complications and continuous prophylaxis will greatly reduce the number of recurrences in patients who have already had an attack of rheumatic fever

It is now well established that therapy of streptococcal infections which eliminates the infecting organism will prevent initial attacks of rheumatic fever and nephritis If the organism is not eliminated the attack rate of rheumatic fever is not altered The preferred method of therapy is either a single injection of 900 000 units of benzathine penicillin or 200 000 to 250 000 units of penicillin V four times daily for at least 10 to 14 days If the patient is sensitive to penicillin, erythromycin or the tetracyclines are given in full doses for 10 to 14 days Treatment should be instituted promptly especially if acute nephritis is to be prevented Therapy instituted after symptoms of the acute respiratory illness have subsided will still prevent the onset of rheumatic symptoms Since the sulfonamide drugs are bacteriostatic they should never be employed for the treatment of streptococcal infections

Once rheumatic fever develops penicillin should be administered in full therapeutic doses in order to eliminate the streptococcus This therapy is advised under the assumption that the organism may be contributing to the rheumatic process Eradication of the streptococcus should alter the disease in a favorable fashion but evidence establishing the efficacy of such therapy is not available

From 20 to 80 per cent of streptococcal infections which occur in individuals who have had an initial attack of rheumatic fever are followed by recurrences Since many streptococcal infections produce no symptoms it is not possible to rely on treatment of the infection for the prevention of recurrences For this reason patients with rheumatic fever or established rheumatic heart disease should be protected continuously against streptococcal disease This is best accomplished by the intramuscular administration of 1 200 000 units of benzathine penicillin once each month Oral prophylaxis which depends upon full cooperation of the patient is obtained by the daily administration of 0 5 to 1 0 Gm sulfadiazine Penicillin may be employed but medication must be given twice daily in doses of 250 000 units Prophylaxis is maintained throughout the year Except in individuals who show no evidence of valvular heart disease or in a few patients in whom the risk of contracting a streptococcal infection is considered negligible prophylaxis is continued indefinitely

Patients with rheumatic valvular heart disease subjected to surgical procedures especially tooth extractions should receive penicillin as a prophylactic measure before and several days after the operation It is believed that such treatment will prevent the development of subacute bacterial endocarditis

The problem presented by the patient with acute nephritis differs from that posed by the patient with rheumatic fever The appearance of a case of acute nephritis in the hospital or physician s office indicates that a nephritogenic type of streptococcus is circulating in the population Since the attack rate of nephritis may be very high following infection with these organisms the physician has a duty to the public to eliminate the streptococcus from both the patient and all contacts Spread of streptococci is especially likely to occur in the home and school Therefore cultures of the throat should be obtained from contacts in these two areas Individuals with positive cultures should receive therapy in a form sufficient to eliminate the organism In addition the urine should be examined microscopically for unapparent cases of nephritis will be found in persons found to have a positive culture

Once the patient has *recovered* from the acute phase of nephritis it is not necessary to institute prophylaxis against streptococcal *infection* Recurrences are rare if they occur at all The most likely explanation for this fact is that the patient acquires lasting immunity against the infecting type of streptococcus and statistically has little chance to be infected with another type possessing nephritogenic qualities It is also possible that the substance responsible for nephritis is antigenic thus antibody

The diagnosis of acute nephritis is frequently not considered in patients who exhibit only pain in the groin or abdomen or gross hematuria Such patients are thought to have acute appendicitis or small renal calculi but careful examination of the urine will show red cell casts which establish the proper cause of the symptoms

The most difficult diagnostic problem is the recognition of exacerbations of chronic glomerulonephritis Here the presenting symptoms may be identical to those exhibited by patients with acute nephritis caused by nephritogenic streptococci Some clue is afforded by the absence of a preceding streptococcal illness the sudden onset of symptoms without a latent period and the finding of a high degree of proteinuria Exacerbations of chronic nephritis are characterized by an insidious onset marked proteinuria and persistent edema Any infection may precipitate the illness Since streptococcal infections are common it is to be expected that individuals with chronic nephritis will acquire these infections The identification of the serologic type of streptococcus becomes important in these patients since the isolation of a type not possessing *nephritogenic qualities may indicate the proper* diagnosis

Patients presenting a nephrotic syndrome may show hematuria and hypertension Here chemical studies of the blood are of assistance The findings of low serum protein and high cholesterol indicate chronic renal disease

Finally increased excretion of red cells is observed in many patients with acute infections In the majority of these the hematuria along with slight albuminuria disappears soon after the temperature returns to normal In contrast following infection with nephritogenic streptococci the hematuria returns and persists for several days or weeks During this second episode of hematuria proteinuria is not a characteristic feature It seems likely that such cases represent a mild form of acute nephritis

Course and Prognosis The course of acute nephritis is extremely variable In hospitalized cases 3 to 5 per cent die In most instances death occurs in patients presenting a syndrome resembling heart failure Since these patients exhibit retention of water oliguria and hypertension it is difficult to determine the pathogenesis of the apparent heart failure Occasionally death is due to uremia convulsive seizures infection or rupture of a cerebral vessel

Two different courses of illness are observed in patients who do not die during the acute phase In one complete recovery is the rule and only rarely do signs of chronic nephritis develop whereas in the other group the majority develops chronic progressive renal disease There is reason to believe that acute nephritis caused by nephritogenic streptococci does not lead to chronic nephritis Patients who give a classical history of a preceding respiratory infection or develop nephritis following scarlet fever rarely develop chronic nephritis (Ellis type I) These patients usually seek medical attention within a few days after the onset of symptoms of nephritis In contrast the patient who exhibits an insidious onset of nephritic symptoms gives no evidence of a recent streptococcal infection shows large amounts of protein in the urine or develops hematuria without a latent period is especially likely to exhibit chronic progressive renal disease The illnesses in this group of patients (Ellis type II) may represent exacerbations of chronic nephritis Recent studies show that the serum from these patients contains no antibody against nephritogenic organisms whereas such antibodies can be demonstrated in many patients who have recovered following an attack of type I nephritis

The clinical signs of nephritis observed following infection with nephritogenic streptococci last only a few weeks Edema hypertension and gross hematuria disappear within a few days or weeks *Persistence of these signs for more than 2 months* is a bad prognostic sign and may indicate chronic renal disease Abnormal numbers of red cells and moderate proteinuria may persist for months in a few patients Individuals who recover from acute nephritis rarely experience another attack

Treatment *Bed rest* is necessary in the early phases of an attack of acute nephritis During the first week or two physical exertion or sudden stimuli such as an alcohol rub or news of death in the family may precipitate severe hypertension pulmonary edema convulsions cerebral hemorrhage or coma If possible the patient should be placed in a single room mild sedation should be administered few or no visitors should be permitted and the number of examinations and procedures should be kept to a minimum Bed rest should be enforced until the blood pressure has become stabilized and signs of edema have disappeared Restricted activity is advisable until the sedimentation rate is normal and the number of red cells excreted is not altered significantly by exercise There is no evidence indicating that activity is harmful to the patient who continues to excrete red cells in moderate numbers during the convalescent period

Patients infected with nephritogenic streptococci who subsequently develop nephritis are especially likely to exhibit abnormal degrees of hematuria during the acute respiratory infection Since this may indicate that some product of these organisms damages the glomerulus directly the organism should be eliminated This is best accomplished by the administration of procaine penicillin in doses of 600 000 units twice daily for 2 weeks

of infection Penicillin and streptomycin in combination exert a synergistic effect against enterococci and are indicated in the treatment of bacterial endocarditis caused by them or in other enterococcal infections not responding to tetracyclines In cases of enterococcal endocarditis a regimen of at least 10 million units of penicillin and 1 Gm of streptomycin daily for 6 weeks is indicated If clinical improvement is not evident within a short time the amount of penicillin should be increased Although 2 weeks of intensive combined chemotherapy has been shown to be adequate in most cases of *Streptococcus viridans* endocarditis at least 6 weeks of therapy is essential in those caused by the enterococci

Streptococcus viridans No "C" polysaccharide which would permit etiologic classification has been demonstrated in members of this heterogeneous group and biochemical reactions have been used to characterize the several subtypes Of those important to man the majority produce greening on blood agar plates although a few strains are nonhemolytic These bacteria are members of the normal throat and mouth flora and only rarely incite disease They frequently invade the blood stream following dental manipulation and indeed following mastication where dental hygiene is poor Their chief pathogenicity is displayed in patients with acquired or congenital vascular lesions where they become implanted following bacteremia and cause the majority of cases of bacterial endocarditis Some patients with atypical pneumonia develop agglutinins to a member of this group streptococcus "MG" The significance of this is not well understood these bacteria apparently are of no etiologic significance in such infections

Anaerobic Streptococcal Infections Anaerobic streptococci have been divided with difficulty into nine groups on the basis of fermentation reactions of five carbohydrates and five organic acids Most strains remain strictly anaerobic but some are able to grow without conditions of anaerobiosis on further subculture These organisms comprise part of the normal body flora being present in the nose and throat gums vagina and intestine They exist as commensals but in appropriate conditions can invade neighboring structures and incite disease Circumstances are most favorable for invasion and infection by anaerobic streptococci when necrotic tissue is present The lochia and necrotic cervical tissue of the parturient uterus devitalized tissue as in the postpneumonic lung or the necrotic tissue resulting from pulmonary infarction are examples The ensuing infection is characterized by further tissue destruction and by the production of foul smelling pus

Anaerobic streptococci occur in mixed culture in many instances often with bacteroides but can be the sole etiologic pathogen The spreading necrosis and foul pus of many pulmonary abscesses are usually attributable to these bacteria which frequently are part of a mixed flora In post partum infections caused solely by anaerobic streptococci the clinical syndromes run the gamut from putrid endometritis with low grade fever foul lochial discharge and a soft tender subinvoluted uterus to septic pelvic thrombophlebitis with resulting metastatic abscess formation throughout the body particularly in the lungs

The rapid accumulation of air in anaerobic streptococcal empyema results in part from gas produced by fermentation of carbohydrates by the bacteria and from the frequent occurrence of bronchopleural fistulas A syndrome simulating clostridial gas gangrene may result from infections of devitalized muscles by gas producing anaerobic streptococci Although the spreading crepitation resembles that of clostridial infection the overwhelming toxemia of the latter is absent

Anaerobic streptococci assume a pathogenic role in some infected human bites Infections of the paranasal sinuses or mastoid cells by these bacteria produce the same picture as infections of these structures by other bacteria On occasion they may extend into adjacent cranial bones with resulting osteomyelitis Direct extension into the brain may occur

Treatment Penicillin remains the drug of choice in anaerobic streptococcal infections Large doses of this antibiotic are indicated and in some infections the tetracycline antibiotics may be effective All attempts should be made to evacuate collections of pus penicillin should be instilled locally into the infections of serous cavities such as the pleura

against the hypothetical nephritogenic toxin might afford a protective mechanism

Individuals who present signs of chronic glomerulonephritis may suffer exacerbations following bacterial infections including those caused by any type of group A streptococcus In these patients the monthly injection of 1 200 000 units of benzathine penicillin may be advisable

Tonsillectomy has been considered effective in preventing rheumatic fever and nephritis There is no evidence to substantiate this suggestion On the contrary the risk of developing rheumatic fever or nephritis is increased because after tonsillectomy the physician is less likely to make the correct diagnosis and therefore less likely to prescribe adequate treatment

114 OTHER STREPTOCOCCAL INFECTIONS

Max Michael Jr

In addition to the group A beta hemolytic streptococci many other streptococci possess a polysaccharide "C" antigen which permits classification into twelve groups (A N) Those of group A however are by far the most common pathogens All these Lancefield types can produce disease in man but with the exception of group D (enterococci) they are rarely incriminated Groups B and C are pathogenic for cattle and horses and on rare occasions may cause sore throat mastoiditis and other purulent infections in man Groups F and G may cause occasional cases of tonsillitis in human beings

Enterococci (*Streptococcus faecalis*) These organisms can be alpha hemolytic beta hemolytic or nonhemolytic The alpha hemolytic strains are confused with *Streptococcus viridans* but can be differentiated easily by their ability to reduce methylene blue and to grow in broth containing 6 5 per cent sodium chloride They are normal inhabitants of the female genital tract the gastrointestinal tract, and to a lesser extent the upper respiratory tract Invasion of contiguous structures or metastases by way of the blood stream are the modes of infection The enterococci are frequently present in the purulent peritoneal fluid following rupture of the appendix They may be the sole etiologic bacteria in infections of the paranasal sinuses mastoids meninges or gallbladder The most frequent site of enterococcal infection is the urinary tract where they are particularly likely to produce disease when obstructive forces such as calculi and prostatic hypertrophy are present They can be the sole etiologic agent in such infections but more often occur in combination with other bacteria particularly enteric organisms When they are isolated from the urine in pure culture their role as pathogens should be carefully determined by appropriate clinical and quantitative bacteriologic methods

Enterococci are responsible for approximately 10 per cent of cases of bacterial endocarditis Because of the therapeutic problems posed this is a particularly treacherous infection The clinical features of enterococcal endocarditis are in the main similar to those seen in *Streptococcus viridans* endocarditis In contradistinction to the latter however its metastatic lesions can become suppurative foci

Therapeutic Implications The antibiotic agents useful in group A beta hemolytic streptococcal infections are also indicated in infections of all other hemolytic streptococci except those of group D the enterococci Infections resulting from these organisms are susceptible to the tetracycline antibiotics the dosage being dependent upon the site

of infection Penicillin and streptomycin in combination exert a synergistic effect against enterococci and are indicated in the treatment of bacterial endocarditis caused by them or in other enterococcal infections not responding to tetracyclines In cases of enterococcal endocarditis a regimen of at least 10 million units of penicillin and 1 Gm of streptomycin daily for 6 weeks is indicated If clinical improvement is not evident within a short time the amount of penicillin should be increased Although 2 weeks of intensive combined chemotherapy has been shown to be adequate in most cases of *Streptococcus viridans* endocarditis at least 6 weeks of therapy is essential in those caused by the enterococci

Section 3 Infections Due to Gram-negative Cocci

115 MENINGOCOCCAL INFECTIONS

Ivan L Bennett Jr

Definition The commonest infection produced by the meningococcus is a subclinical nasopharyngitis or upper respiratory carrier state In a relatively few individuals this is followed by invasion of the blood stream with involvement of the meninges and other sites or fulminating sepsis with rapid circulatory collapse and death

Etiology *Neisseria meningitidis* or *intracellularis* a gram negative coccus was shown to be the cause of cerebrospinal or "spotted" fever by Weichselbaum in 1887 In stained smears of exudates the organisms appear as biscuit shaped single cocci or *diplococci frequently within polymorphonuclear* cells closely resembling gonococci The meningococcus grows best when fresh inocula are incubated in carbon dioxide (candle jar) on media containing blood serum or ascitic fluid chocolate agar is frequently used Like other *Neisseria* the organism gives a positive oxidase test its colonies on solid medium turning purple when exposed to 1 per cent p aminodimethylanilidemonochloride The meningococcus is identified by its ability to ferment glucose and maltose The gonococcus ferments glucose only and nonpathogenic *Neisseria* (*N flava N sicca N catarrhalis*) ferment glucose maltose and sucrose or none of these sugars Meningococci have been classified into serologic types but these types are presently of interest only on epidemiologic grounds The clinical diseases produced by all serotypes are identical and all are susceptible to sulfonamides penicillin and several other antibiotics

Epidemiology Under ordinary circumstances 2 to 5 per cent of normal individuals harbor meningococci as part of the flora of the nasopharynx Studies such as that of Phair and Schoenbach in 1944 have shown that crowding during the winter months is associated with a rise in the asymptomatic carrier rate to as high as 40 to 90 per cent As the rate rises cases of systemic meningococcal infection appear but it is clear that fewer than 1 per cent of parasitized individuals develop serious illness The circumstances leading to spread of infection beyond the nasopharynx are unknown although several factors have been suggested (1) failure of nasopharyngeal infection to confer immunity—this is unlikely to play a role in that relatively few carriers are found to possess serum antibodies (2) in vivo development of invasive mutants (3) sudden introduction of a virulent strain into a population group (4) concomitant viral infection of the nose and throat—in army outbreaks recruits have been more susceptible to meningococcal infections during the seasoning period when upper respiratory infections are numerous Malnutrition trauma and debilitating disease seem to play no role Disseminated meningococcal infection is commoner in males and below the age of five years Mortality is greatest at the extremes of life Case to-case transmission is rarely demonstrated in epidemics and the frequency of asymptomatic carriers makes it obvious that strict isolation of clinical cases is unjustified Administration of sulfonamides or penicillin *to a patient results in rapid disappearance of* meningococci The prophylactic use of oral sulfadiazine in a dose of 1 to 2 Gm to a population reduces the carrier rate abruptly and can abort an epidemic in a school army post or other limited group

Pathogenesis Spread of organisms occurs by droplet infection the upper respiratory tract is the usual portal of infection although rare instances of isolated meningococcal conjunctivitis in which the eye was apparently a primary point of entry have been reported About 75 per cent of systemic infections are preceded by upper respiratory symptoms but the role of the meningococcus in these symptoms is difficult to assess Spread of infection beyond the nasopharynx is now known to occur almost exclusively via the blood stream Purulent meningitis the commonest metastatic complication is preceded by a bacteremia as are arthritis and rarer localizations such as ophthalmitis pneumonia pericarditis endocarditis empyema orchitis salpingitis and epididymitis Bursitis and tenosynovitis may complicate articular involvement which next to meningitis is the most frequent complication of meningococcemia occurring in about 3 per cent of cases

The meningococcus possesses an endotoxin similar to those of gram negative bacilli injection of these materials into experimental animals results in fever vascular damage shock and other toxic changes There is much to indicate that endotoxin may be responsible for the rapidly fatal course of fulminating meningococcemia with hemorrhagic skin lesions and circulatory collapse

Autopsy findings include widespread dermal and

visceral hemorrhage purulent meningitis basilar in distribution and in older cases extensive meningeal scarring and hydrocephalus Meningitis is often absent in cases of fatal meningococcemia the main findings consisting of large hemorrhages in the various organs and tissues Histologic examination reveals widespread thrombosis of small vessels and numerous areas of necrosis containing large numbers of meningococci The adrenal cortex may be grossly hemorrhagic and almost invariably contains microscopic lesions of severe and extensive degeneration

Clinical Manifestations The course of disseminated meningococcal infection is highly variable Clinically there are three main types *meningococcemia meningitis* and *fulminating sepsis*

Meningococcemia Invasion of the blood by meningococci may be followed almost immediately by meningitis or patients may be seen during the bacteremic stage Prodromal symptoms of upper respiratory irritation are followed by abrupt onset of fever often with a rigor myalgia headache nausea and particularly in children diarrhea Extreme tenderness of the soles of the feet without signs of local inflammation is highly suggestive of the disease many patients are thought in the beginning to have influenza or some other grippelike illness There is usually a polymorphonuclear leukocytosis of 12 000 to 40 000 per cubic millimeter The diagnosis is facilitated by the development of *skin lesions* in about three fourths of the cases The rash from which the disease derived the name "spotted fever" consists of petechiae of the skin and mucous membranes and typical bright pink nonpruritic tender macules or papules 2 to 10 mm in diameter over the extremities and trunk These lesions sometimes have hemorrhagic centers Hemorrhagic vesicles and larger cutaneous ecchymoses ("suggillations) sometimes occur Lesions may be few and careful search is essential in some cases the eruption is so profuse and rapid in onset that new lesions can be seen to appear within minutes

Splenomegaly is inconstant in the early stage conjunctivitis hemorrhages in the fundus oculi and arthritis are sometimes present but joint involvement is more frequent in the chronic stage of the disease

Chronic meningococcemia is characterized by periodic bouts of fever arthralgia or arthritis and recurrent cutaneous lesions The disease may continue for many months Splenomegaly is usually present and each recurrence is accompanied by polymorphonuclear leukocytosis Patients with this peculiar infection are usually asymptomatic between attacks The disorder is sometimes mistaken for malaria or allergic purpura The skin lesions can take any of the forms described above The majority of patients become asymptomatic after several weeks or months even without treatment a few finally develop endocarditis or meningitis

Meningitis In most patients the bacteremic stage is followed within a few hours or days by the onset of acute purulent meningitis with severe headache nuchal rigidity nausea vomiting disorientation and stupor Impairment of hearing occurs early and what appears to be lack of cooperation or inability to answer questions is sometimes attributable to this There is high fever respirations may be periodic and skin lesions are frequent Signs of meningeal irritation are prominent but papilledema is unusual

Fulminating Infections Meningococcemia can produce death within a few hours with the "Waterhouse-Friderichsen" syndrome of bacteremia massive skin hemorrhage and shock This triad can result from pneumococcal streptococcal or other infections but the meningococcus is the usual etiologic agent The complex is commoner in children below the age of five years

The onset is abrupt with fever and nonspecific discomfort until dermal petechiae appear and rapidly enlarge into areas of confluent purpura The blood pressure falls rapidly although the skin may remain warm to the touch Patients usually remain alert Ordinarily the infection leads to death within several hours Because bilateral adrenal hemorrhage is frequently present at autopsy and microscopic adrenal necrosis is invariable the role of acute adrenal insufficiency in this infection has been much argued The use of adrenal steroids is probably justified but therapeutic regimens have not been evaluated systematically In patients who recover oliguria may persist for 18 to 24 hr after blood pressure stabilizes and extensive sloughing of the skin lesions or loss of extremities from gangrene often prolongs convalescence Meningitis is not a usual feature

Rarely meningococcal infection may take an *encephalitic* course in which signs of meningeal infection are scanty but extensive cerebral involvement leads to stupor coma and death within a few days Circulatory collapse is not a prominent part of the picture except terminally Progressive signs of neurologic disturbance and papilledema are the outstanding manifestations

Laboratory Findings Polymorphonuclear leukocytosis is the rule In meningitis there is elevation of spinal fluid pressure and the fluid is cloudy (it may be clear early in the disease) containing from a few hundred to 40 000 polymorphonuclear cells per cubic millimeter Protein is elevated and the glucose content is low Albuminuria and microscopic hematuria are not infrequent and transient glycosuria is sometimes present

Specific diagnosis depends upon demonstration

of the meningococcus in smears or cultures of spinal fluid or material aspirated from skin lesions or joints Smears of body fluids stained with methylene blue are useful for detection of the organism *which is frequently contained in polymorphonuclear* leukocytes its gram staining reaction should be confirmed Confusion sometimes arises with *Hemophilus influenzae* which is gram negative and pleomorphic It is sometimes impossible to find meningocci in stained sediment of spinal fluid this is more likely to occur in this disease than in any other pyogenic infection of the meninges

So numerous are meningocci in the blood that it is not unusual to find them in smears of buffy coat material The skin lesions often contain many organisms also the skin around the lesion should be pinched up the lesion punctured and a drop of tissue fluid (not blood) smeared and stained

Material taken for culture should be inoculated immediately (preferably at the bedside) onto chocolate agar and incubated in a candle jar Meningococci can usually be cultured from the nasopharynx

Complications *Herpes labialis* is common in meningococcal infections particularly in meningitis Urinary retention is often a problem and patients must of course be guarded against the usual complications of coma including aspiration

Chronic hydrocephalus was formerly seen with considerable frequency it is now rare Transient *palsies of cranial nerves* occur and usually clear completely within 6 weeks *Blindness hemiplegia, myocarditis* with heart failure and *localized meningococcal infections* in other sites are all very rare *Deafness* of a degree detectable by audiometry is present in about 5 per cent of patients who recover from meningitis it is usually unilateral and severe impairment of hearing is now unusual

It is not unusual for patients to complain of fatigability headache dizziness and insomnia for many months after recovery It is believed that many of these symptoms result from injudicious psychologic management of patients during convalescence

Diagnosis The clinical diagnosis of meningococcal infection is easily made in patients with fever skin lesions and meningitis Diseases with which confusion can arise include other forms of meningitis bacterial and nonbacterial endocarditis the common exanthemas subarachnoid hemorrhage rickettsioses thrombocytopenic and other purpuras and drug eruptions Once the meningococcus is suspected as the etiologic agent the diagnosis can usually be established by demonstration of the organisms

Treatment When the clinical diagnosis of meningococcal infection has been made and specimens have been obtained for culture *specific antimicrobial* therapy should be instituted immediately Sulfonamides and penicillin are equally effective Sulfadiazine sulfamerazine and Gantrisin are excellent agents In patients with hypotension and oliguria *dosage should be reduced until urine flow is re*established Penicillin in a dosage of 1 2 to 2 4 million units per day in divided doses has the advantage of immediate bactericidal action in contrast to the 4 to 6 hr delay before sulfonamides begin to act for this reason penicillin is preferable in fulminating infections where a slight delay may be crucial Intrathecal administration of penicillin in a dose of 5 000 to 10 000 units is permissible but unnecessary The initial dose of penicillin should be given intravenously to patients with circulatory collapse Chloromycetin the tetracycline derivatives and other antibiotics are effective in meningococcal *infections but have not replaced sulfonamides* and penicillin as the drugs of choice There is no advantage to combining sulfonamides and penicillin although this is frequently done

Supportive therapy includes the usual precautions in patients who are delirious or stuporous sedation and relief of headache with Demerol which is less likely to aggravate urinary retention than are opiates Maintenance of fluid balance is particularly important if sulfonamides are given the majority of these patients are somewhat dehydrated when first seen because of vomiting and lack of intake There is nothing to be gained of course by overloading hypotensive patients with fluid during the oliguric phase of fulminating meningococcal infection It is extremely important to keep a careful *record of blood pressure and fluid balance* in all patients with meningococcal disease until a definite therapeutic response is evident

In patients with overwhelming meningococcemia and circulatory collapse prompt and vigorous antimicrobial therapy is the most important step Pressor amines may be given by intravenous infusion as may adrenal steroids the evidence for the effectiveness of these agents is incomplete and recovery has been reported without their use but the usual practice at present is to give them It is worth remembering that individuals with the Waterhouse Friderichsen syndrome are extremely susceptible to the local necrotizing action of pressor amines and extravasation into the tissues should be carefully avoided Large amounts of blood and plasma will not influence the hypotension and should not be given

The response of meningococcemia to treatment is dramatic defervescence usually occurs within 24 hr Patients with meningitis may continue to have some fever disorientation and meningeal signs for 2 to 5 days this should not lead to a change in chemotherapy Relapse is almost never

seen and although documented second attacks of meningococcal meningitis have been reported they are extremely rare

Prevention The frequency of carriers and the effectiveness of chemotherapy in rendering patients noninfectious makes the use of strict isolation technique for meningococcal infections both ineffectual and fallacious As has been mentioned the wholesale administration of 1 to 2 Gm sulfadiazine will reduce the carrier rate and abort an epidemic in closed populations When continued contacts with the general public are maintained however the effectiveness of this procedure is likely to be transient

116 GONOCOCCAL INFECTIONS

Max Michael Jr

Definition Gonococcal infections comprise a group of syndromes with varied manifestations produced by a single etiologic agent the gonococcus (*Neisseria gonorrhoeae*) The organism has a predilection for the mucous membranes of the genital tract of both sexes but may incite disease processes in any region of the body particularly in synovial tissues and on serosal surfaces

Etiology The gonococcus is a gram negative oval coccus belonging to the genus *Neisseria* In stained films of purulent exudates the organisms appear predominantly in pairs the opposing surfaces being flattened or concave resulting in a characteristic biscuit or kidney bean–shaped appearance In cultures however there is considerable variation in size and shape of single cells and the flattening of opposing surfaces is seldom evident The gonococcus grows best on solid media enriched with protein such as blood plasma or ascitic fluid Moist atmosphere with 2 to 5 per cent carbon dioxide as attained in a candle jar" assists growth of the organism It is differentiated from other members of the genus *Neisseria* by its fermentation reactions on glucose maltose and sucrose and by agglutination reactions It is thought that two or more antigenic strains of the gonococcus exist Both nucleoprotein and polysaccharide substances have been identified in the cell but their relationship to more precise antigenic divisions has not been conclusively demonstrated The gonococcus contains an endotoxin No true exotoxin has been isolated

Epidemiology Gonococcal infection of the genital tract or gonorrhea is nearly always acquired by sexual exposure and is in fact the most common venereal disease It can be transmitted by sexual partners who have no symptoms of the infection It is difficult to estimate the total number of new cases of gonorrhea each year but it is estimated that approximately one million cases are acquired in the United States each year The lack of interest of the public and physicians alike concerning gonorrhea and the tendency to attach relatively minor significance to the infection have detracted from general appreciation of its true public health significance and its seriousness Although many cases of gonorrhea have relatively mild symptoms severe complications including a high degree of sterility may result from the disease

Gonococcal conjunctivitis of the newborn (ophthalmia neonatorum) is acquired in the infected birth canal but has been practically eliminated by routine instillation of silver compounds or penicillin into the eyes of the newborn Vulvovaginitis in young girls is now known to be nongonococcal in origin in many instances Most of the gonococcal vulvovaginitis can be traced to sexual contact infected linen and toilet seats play little or no role in the spread of this form of the disease

It has been demonstrated that individuals may harbor the gonococcus in their prostatic secretions for as long as 7 years without symptoms and hence serve as asymptomatic carriers

Pathogenesis In the majority of instances the gonococcus gains access to the body by way of the genital tract Less frequent sites of initial infections are the conjunctivas and rectal mucosa The type of mucosa found in a particular part of the genitourinary tract determines to a large extent the susceptibility of that tissue to gonococcal infection Stratified squamous epithelium which covers the external genitalia of both sexes extends for ap

proximately 2 cm into the male urethra and lines the adult female vagina is not susceptible to infection Columnar epithelium which lines the anterior urethra urethral glands prostatic ducts and prostate seminal vesicles vas deferens and epididymis in the male and Skene s Bartholin s urethral and cervical glands fallopian tubes and endocervix in the female furnishes fertile soil for growth of the *gonococcus* Transitional epithelium which lines the posterior urethra of the male the proximal half of the urethra in the female and the bladder of both sexes is susceptible to invasion by gonococci Within a short period of time however infection is spontaneously eradicated from surfaces lined with this type of epithelium unless they are being bathed in exudate coming from an active lesion Adequate drainage of infected glands and tissues formerly was regarded as essential for recovery before chemotherapeutic agents were available When no such drainage took place destruction of tissue and abscess formation with eventual fibrosis and cyst formation ensued Now however this does not appear to be such an important factor for recovery

From the genital lesion the infection may take any of the following courses (1) it may be completely eradicated either spontaneously or as the result of therapy (2) it may be spread locally by way of the lymphatics or by direct extension to involve other organs of the genitourinary tract (3) it may remain hidden in recesses of the genital mucosa not causing symptoms but producing the carrier state (4) it may invade the blood stream and set up metastatic lesions most important of which are arthritis and endocarditis

Since it is not possible to culture the gonococcus from many of the metastatic lesions of gonorrhea it has been suggested that these lesions represent an allergic response to antigenic fractions of the gonococcus or to tissues which have been altered antigenically in some fashion by the organism This however has not been definitely established

It is possible to produce acute gonococcal infection by reinfecting a person with chronic gonorrhea It is obvious that there is little if any immunity to gonorrhea but this point will need clarification when different strains of the gonococcus are better identified Attempts to evoke immunity to gonorrhea by vaccination have been unsuccessful

Manifestations ***Gonococcal Infection of Genital Tract*** After an incubation period of from 3 to 5 days gonorrhea in the *male* begins as an acute anterior urethritis manifested by purulent urethral discharge and burning on urination If not properly treated infection may spread to the posterior urethra with symptoms of frequency urgency and terminal hematuria Perineal discomfort may occur The prostate and seminal vesicles may also be involved and this may result in acute retention of urine and pain in the suprapubic region Acute seminal vesiculitis may cause high fever and pain that is referred to the suprapubic inguinal and sacral regions or to the hip on the involved side Puzzling syndromes of obscure fever and pain in the above mentioned regions are occasionally due to seminal vesiculitis Acute prostatitis may be accompanied by urinary retention elevation of temperature and the feeling of fullness in the rectum Rectal examination discloses the enlarged tender prostate gland More serious involvement is that of acute epididymitis which is accompanied by pain in the epididymis swelling and fever The resulting tissue destruction is responsible for many cases of sterility in males

Gonococcal urethritis is to be distinguished from nonspecific urethritis an entity in which the exudate is more watery and in which local symptoms of gonorrhea are absent there is furthermore no improvement following penicillin therapy Gram stain of the urethral exudate usually reveals gonococci when they are the etiologic agent more or less by definition these organisms are absent in nonspecific urethritis

The chronic stage of gonorrhea may be asymptomatic or may be manifested by a small amount of mucoid urethral discharge occurring in the morning (gleet) or by urgency and frequency of urination Chronic prostatitis in a small number of patients is due to previous gonococcal infection

Gonorrhea in the *female* also begins as an acute urethritis with frequency and burning on urination and purulent discharge Cervicitis may be present at the same time resulting in a profuse purulent vaginal discharge There may be local spread to Skene s or Bartholin s glands with resulting acute or chronic infection in these organs Spread from the cervix into the fallopian tubes produces the syndrome of acute salpingitis or pelvic inflammatory disease (P I D) This is manifested by severe pain in the lower abdomen with local spasm and tenderness high fever and leukocytosis vaginal discharge and painful urination Recurring bouts of salpingitis are frequent with involvement of the ovaries destruction of tissue formation of abscesses and palpable masses resulting in the frozen pelvis This is an important cause of sterility

Acute salpingitis must be differentiated chiefly from acute appendicitis and ectopic pregnancy though all causes of acute lower abdominal pain are to be considered A vaginal discharge caused by the gonococcus is to be differentiated from vaginal discharge caused by *Trichomonas vaginalis* cervical erosions and other local gynecologic disorders

Gonorrheal vaginitis in the *immature female* is not so common as formerly believed Many cases

previously considered to be gonococcal in origin are actually due to other microorganisms Because of the nature of the vaginal epithelium in the immature female the gonococcus finds susceptible tissue and causes purulent discharge redness of the vulva and introitus with accompanying malaise and some fever

Arthritis Gonococcal arthritis an acute inflammatory process is the commonest and most disabling metastatic complication of this disease and is more frequent in patients who have had multiple attacks of urethritis Although the incidence of gonorrhea continues at a high rate that of arthritis appears to be decreasing This probably results from the more prompt eradication of the organisms from the genital tract before metastatic or sensitized lesions can develop

PATHOGENESIS AND PATHOLOGY Two clinical syndromes are associated with gonococcal arthritis In approximately 25 per cent of the patients the gonococcus can be cultured from the synovial fluid in these patients the disease manifests itself as a specific infectious arthritis In the remaining cases the synovial fluid is sterile and some features of the disease follow certain of the patterns of rheumatoid arthritis In the former group the gonococcus reaches the joint by way of the blood stream and sets up a purulent infection In the latter group it is not certain whether the organisms reach the joint spaces and are rapidly destroyed or whether the arthritis is the result of sensitization of the synovial tissues by antigenic fractions of the gonococcus without actual bacterial invasion of the joint Pathologic material demonstrate certain differences in the two types In the infected type of arthritis there is an extensive inflammatory reaction of the synovial tissue with destruction of the superficial layer of synovial cells In the noninfected type of arthritis the synovial tissue proliferates thickens and is infiltrated by perivascular and subsynovial collections of lymphocytes plasma cells and macrophages Occasionally neutrophils are present The extensive exudative reaction is not seen The superficial synovial layer is not completely destroyed and in some phases may be seen to proliferate The findings in the former group are those of an acute bacterial infection while in the latter group they suggest the picture of a hypersensitivity reaction

The cell count of aspirated synovial fluid varies from 1 800 to 160 000 white cells per cubic millimeter in general being higher in those cases with infected fluids The fluid always has the characteristics of an exudate with predominance of polymorphonuclear leukocytes The sugar content of the synovial fluid is decreased but this is of little help in differentiating gonococcal from other forms of acute arthritis

Destruction of articular cartilage may be noted as early as 3 weeks after the onset of arthritis These changes are most apt to be seen in cases with infected synovial fluid Associated with the changes in the joint are periarticular inflammatory reactions which may later fibrose and contribute to ankylosis of the joints

CLINICAL FEATURES *Arthritis* most commonly occurs 1 to 3 weeks following genital involvement but at times the interval may be prolonged to months or years Factors predisposing to arthritis include pregnancy pelvic operations or instrumentation for ureteral stricture all of which may cause latent infection to flare up

The arthritis of gonococcal infection is polyarticular in about 85 per cent of the cases The joints most frequently involved are the knees ankles wrists metacarpophalangeals and shoulders in that order though any joint in the body may become infected The first signs noted are those of malaise and fleeting aches in several of the large joints Within 24 to 48 hr pain becomes more severe and more persistent After 3 or 4 days two or more joints become exceedingly painful and distended with fluid The overlying skin becomes red and the slightest motion causes severe pain Marked muscle spasm occurs around involved joints and is responsible for the rapid development of deformities A striking and rapid muscle atrophy adjacent to involved joints is a common feature

The course of gonococcal arthritis is exceedingly variable Some cases may be mild with transitory aches in the joints which clear rapidly in a few days without residua At the other extreme are cases that may progress to permanent bony ankylosis of the joints This termination occurs primarily in cases with infected fluids which are untreated and involves principally the smaller joints of the wrists and hands

In a small group of patients a picture resembling rheumatoid arthritis occurs as a sequel to gonococcal infection It is not certain whether this represents gonococcal arthritis evolving into the rheumatoid picture or whether it is simply rheumatoid arthritis precipitated by the gonococcal infection Rheumatoid nodules are not seen

The systemic response varies considerably Fever between 100 and 102 F is usually present though extremes from normal to 105 F may be observed Chills are infrequent but may be seen particularly in patients with monarticular involvement It is in this group that bacteria are cultured from the joint fluid

A characteristic feature is tenosynovitis This appears in approximately 40 per cent of the patients and occurs most frequently about the wrists dorsum of hands and feet and around the internal and external malleoli Tenosynovitis may be confused with arthritis unless careful evaluation of

joint mobility is made Occasionally tenosynovitis may be the only sign of the gonococcal infection The occurrence of tendon sheath involvement is more frequent in gonococcal arthritis than in any other type of arthritis and may be a valuable diag nostic sign Acute bursitis is sometimes noted

Catarrhal conjunctivitis occurs in approximately 15 per cent of cases and may also be helpful in diagnosis Organisms have not been cultured from these lesions The conjunctivitis may precede ac company or follow the arthritis A less frequent but more serious ophthalmic manifestation is irido cyclitis which may lead to blindness

Keratodermia blennorrhagica an interesting but rare form of cutaneous lesion may accompany gonococcal arthritis This lesion occurs most fre quently on the plantar surface of the feet and con sists of thickening of the skin some of which may become necrotic There is sharp demarcation be tween involved areas and the surrounding skin

The diagnosis of gonococcal arthritis can be simple particularly in patients with acute poly arthritis following a urethral discharge in which the gonococcus has been demonstrated Associated conjunctivitis and tenosynovitis are characteristic and may be of help in diagnosis

In the differential diagnosis rheumatic fever rheumatoid arthritis in the acute stage and Reiter s disease offer the greatest problems Gout may also imitate this disease The use of salicylates may be of some diagnostic aid since gonococcal arthritis usually does not respond as dramatically as does rheumatic fever The most confusing syndrome to be differentiated is Reiter s disease which is char acterized by urethritis arthritis and conjunctivitis (see p 1154) It is only by correlation of careful clinical observations of the patient the course of the illness response to chemotherapy precise bac teriologic studies and the judicious interpretation of the gonococcal complement fixation test that gonococcal arthritis may be differentiated from the conditions mentioned above In cases of gonococcal arthritis in which response to penicillin is relatively prompt this therapeutic test serves as an important diagnostic aid

Perihepatitis An infrequent complication of gon orrhea in the female is the occurrence of upper abdominal peritonitis or perihepatitis Gonococci have not been cultured directly from the lesions but the organisms are assumed to reach this area by direct extension over the posterior peritoneal gutter When the lesions heal characteristic "violin string adhesions are formed The symptoms of perihepatitis which may occur as long as 5 years after the initial attack of gonorrhea consist of a sudden onset of sharp pain in the upper abdomen with a moderate elevation of temperature The pain may be referred to the shoulder and is exaggerated by coughing or deep breathing A friction rub is occasionally heard over the liver and infrequently small pleural effusions develop on the side of the lesion If untreated perihepatitis subsides gradually over a period of 1 to 4 weeks No incapacitating sequelae are known

Gonococcal Endocarditis The gonococcus is a rare cause of bacterial endocarditis The clinical picture is similar to that of acute endocarditis caused by other microorganisms Involvement of the valves of the right side of the heart is not in frequent A double daily temperature elevation is occasionally seen and may be of some assistance in diagnosis Arthritis frequently coexists Peripheral emboli occur as in other forms of endocarditis Another characteristic feature is involvement of normal heart valves in 90 per cent of the cases

Bacteremia Transient invasion of the blood stream by the gonococcus probably occurs fre quently but is accompanied by no symptoms other than chill in a few patients with gonococcal ar thritis Constant invasion of the blood stream how ever produces a bacteremia characterized by chills fever polyarthritis prostration and a macular erup tion of the trunk and extremities The rash rapidly becomes vesicular pustular and hemorrhagic This rare complication of gonorrhea is more common in females Until chemotherapeutic agents were avail able recovery occurred in from 3 weeks to 3 months

The dissemination of the gonococcus by way of the blood stream accounts for some of the rare manifestations of the disease such as meningitis periostitis suppurative myositis perichondritis liver abscesses and myelitis It is apparent that few if any regions or organs of the body are free from attack by the gonococcus

Laboratory Diagnosis The chief laboratory meth ods of diagnosis depend upon the demonstration of the organism by smear and by confirmatory cultures In smears of purulent exudate stained by the Gram method the organisms are seen as the characteristic gram negative biscuit shaped diplococci often located within the cytoplasm of polymorphonuclear leukocytes This is sufficient evidence for a positive diagnosis but failure to demonstrate the organism does not rule out gonorrhea cultural methods must be undertaken The most commonly used media are chocolate agar and Pizer s media the latter being a basic medium enriched with plasma and contain ing Nile blue to inhibit other organisms The tech nique of obtaining cultures is very important and extreme care must be taken to avoid excess con tamination Moist fresh inocula must be used The cultures of gonococci can be identified easily by their color reaction to the oxidase reagent This reagent (1 per cent solution of tetramethyl p phenylenediamine hydrochloride) when po

over the suspected plate produces a deep purple discoloration of *Neisseria* colonies Best results are obtained from direct cultures of urethral prostatic or cervical exudates When these are not available cultures of the urine sediment are often of value

In culturing joint fluid for the gonococcus it is not adequate merely to streak a loopful of the material on the culture medium Preferably the plate should be flooded with about 0 5 ml of the fluid Inoculation of the sediment from centrifuged fluid is helpful Often it is possible to obtain a positive culture when joint fluid is not available by injecting a few milliliters of physiological saline solution into the periarticular structures and withdrawing some of this for culture

The complement fixation test devised by Price is of considerable value in the differential diagnosis of gonococcal arthritis particularly in cases in which a history of gonococcal infection cannot be obtained and from which gonococci cannot be recovered on culture Antibodies may appear as late as 6 weeks after the onset of arthritis and may persist for months after infection has been eradicated A changing antibody titer is considered to be diagnostic The test appears to be quite specific

Treatment With the introduction of effective chemotherapeutic agents the treatment of gonococcal infections has undergone radical changes Local therapeutic manipulations now have little place in the management of gonorrhea The sulfonamide compounds were widely used until penicillin was introduced However a large number of strains of gonococci resistant to sulfonamides have appeared after several years of such therapy and at present few gonococcal infections are cured by sulfonamides To date however only rarely have gonococci been reported resistant to penicillin The gonococcus is exceedingly susceptible to this antibiotic which at present is the drug of choice Chlortetracycline chloramphenicol and oxytetracycline are all effective in the treatment of gonorrhea However the over all results with penicillin are still better than most reported results with these agents and their use is recommended only in the case of a patient known to be sensitive to penicillin

Relatively small doses of penicillin are needed for the cure of genital infections Two injections of 300 000 units of procaine penicillin are effective in the great majority of cases If there has been no change in the character of the exudate or if gonococci persist after 3 or 4 days then the patient should be re treated with 300 000 units of procaine penicillin in a single injection Oxytetracycline or chlortetracycline in doses of 0 5 Gm initially and 0 5 Gm 6 hr later may be used for the rare case that still does not respond or for the patient with known penicillin sensitivity

A watery urethral discharge is noted in as high as 20 per cent of male patients after the gonococcus has been eradicated by penicillin This discharge is noninfective but its exact nature is not known The small doses of penicillin administered for the treatment of gonorrhea may delay the appearance of syphilitic lesions and follow up studies including serologic tests for syphilis for 6 months must be made with this fact kept in mind Studies carried out in military populations have indicated that 250 000 units of oral penicillin given a few hours after exposure serves to prevent gonorrhea There is no evidence that the development of syphilis is masked by such a dose

Penicillin is also the drug of choice in the treatment of gonococcal arthritis but the small doses that are used in cases of urethritis are inadequate for arthritis A satisfactory regimen consists of one daily injection of 600 000 units of procaine penicillin for 7 to 10 days It is not necessary to instill penicillin into the synovial cavities since this antibiotic diffuses readily into the joint spaces The response to chemotherapy is often not striking and 5 to 7 days may be required for the temperature to return to normal In many cases the arthritis does not subside completely and may smolder for a period of months with occasional exacerbations accompanied by further heat and swelling Occasionally during the course of penicillin therapy joints not previously involved become distended with fluid Many authors feel that this syndrome represents rheumatoid arthritis precipitated or aggravated by the gonococcal infection the writer prefers to regard it as a manifestation of gonococcal arthritis

Physical therapy is an important adjunct in the management of gonococcal arthritis The acutely inflamed joint should be splinted to avoid contractures The judicious use of heat gentle massage and early guarded passive motion are similarly advised in selected cases Artificial fever therapy may be of value in cases resistant to chemotherapy Removal of fluid from distended joints often affords marked relief from pain

Penicillin is also the drug of choice for *other complications* of gonorrhea It has been used locally in ophthalmia neonatorum The dose and duration of therapy must be suited to the syndrome

seen in this condition and liver abscess is one of its complications

Omphalitis Infection of the umbilical stump in newborn infants by colon bacilli can lead to bacteremia (Winckel s disease) that is usually fatal

Bacteremia While organisms can invade the blood in almost any type of coliform infection bacteremia is especially common in pyelonephritis It usually begins with a rigor and high fever Most patients are prostrated slight icterus is not uncommon and even after a single transient episode hypotension of several hours duration is often observed Profound circulatory collapse is more likely to occur in patients with bacteremia due to gram negative organisms including the coliform bacilli *Pseudomonas Proteus Salmonella* and others (see Meningococcemia p 871) than with gram positive species Shock is more frequent in older individuals and is a poor prognostic sign There is no specific treatment moderate amounts of blood or plasma pressor amines such as Levophed or Neo-synephrine and adrenal steroids can be given but these measure should not lead to neglect of the important procedure of initiating vigorous antibacterial therapy Circulatory collapse is sometimes the first sign of coliform bacteremia and especially in patients with diabetes known urinary tract infection history of recent abortion or blood dyscrasias such as leukemia the sudden onset of shock should call to mind the possibility of infection

Escherichia coli bacteremia is occasionally seen in patients with hepatic cirrhosis in the absence of any obvious primary focus of infection The mechanism of entry of the organisms into the blood in these patients is unknown

Pyogenic Infections Coliform organisms are capable of producing abscesses in various parts of the body (see p 958) Diabetic patients are particularly prone to infection by these organisms and small abscesses at the sites of insulin injections are sometimes seen Coliform infection frequently complicates and greatly worsens ischemic gangrene of the extremities An interesting and important feature of coliform infections and abscesses in diabetes (and occasionally in nondiabetic patients) is the production of large amounts of gas in the tissues crepitation is often detectable and the gas may be visualized by x ray It has been suggested that the gas production is related to high glucose content of diabetic tissues An erroneous diagnosis of clostridial infection is often made in these circumstances

Gastrointestinal Disease There are several good epidemiologic studies incriminating certain strains of *E coli* in the etiology of outbreaks of neonatal diarrhea In several outbreaks of adult gastroenteritis there has been highly suggestive evidence that a paracolon bacillus produced the illness In view of the close resemblance of some paracolon bacilli to the *Salmonella* group it is not surprising that occasional strains might produce gastroenteritis in man

Treatment The management of bacteremic shock has been discussed The incision and drainage of localized suppurations is important in coliform infections The general measures for pyelonephritis are discussed on p 969

A variety of chemotherapeutic agents is available but none is regularly effective against all coliform bacilli and in any serious infection the drugs should be chosen with the guidance of sensitivity tests of the infecting strain Chloramphenicol or the tetracycline derivatives in an oral dosage of 2 Gm daily alone or in combination with 1 to 2 Gm streptomycin intramuscularly is likely to be effective Nitrofurantoin (p 824) and the sulfonamides are sometimes effective for urinary tract infections Neomycin (p 823) is toxic but is usually highly effective against organisms of this group and is worth using in any serious uncontrolled infection

117 COLIFORM BACTERIAL INFECTIONS

Ivan L Bennett Jr

Etiology The coliform bacteria are gram negative bacilli which normally inhabit the human intestinal tract similar organisms that occur in soil or vegetation are often included in the group The best known coliform bacilli are *Escherichia coli* (the colon bacillus) and *Aerobacter aerogenes* These two species ferment lactose and although they are harmless saprophytes in the intestinal tract both are capable of producing severe infections if introduced into other tissues The ability to ferment lactose was formerly regarded as an important differentiating characteristic between the saprophytic coliforms and the nonlactose fermenting enteric pathogens of the *Salmonella* and *Shigella* groups It is still a useful property in the laboratory but it is now recognized that there is no sharp dividing line between pathogenic and nonpathogenic species but rather there is a gradual biochemical and antigenic transition through an intermediate group of organisms the paracolon bacilli The paracolon group includes organisms that ferment lactose slowly or not at all the so called Arizona Ballerup Bethesda and Providence bacteria are paracolon bacilli Biochemically or even serologically many of them are extremely difficult to distinguish from *Salmonella* species The paracolon bacilli can produce pyogenic infections in extraintestinal sites and in addition accumulating evidence indicates that some species are capable of producing gastroenteritis in man

The tests commonly employed in differentiating the members of the coliform group are sugar fermentation the Voges Proskauer reaction methyl red test citrate utilization and serologic identification *Alcaligenes fecalis* is another normal coliform inhabitant of the bowel which does not ferment lactose and is sometimes confused with enteric pathogens on SS or desoxycholate agar plates

Because the types of infections produced and susceptibilities to chemotherapeutic agents are closely similar for *E coli* and *A aerogenes* it is customary in many clinical laboratories to report a culture as containing coli aerogenes" bacilli without differentiating between them biochemically

The presence of coliform organisms in water or feces is regarded as presumptive evidence of fecal contamination in public health and sanitary bacteriologic testing

Pathogenesis Coliform organisms may be transported from the intestinal tract to other parts of the body by way of the lymphatic vessels or blood stream or they may be spread by fecal contamination Histologically the lesions produced in various body tissues show typical acute inflammation with pus and abscess formation There is a common misconception that coliform bacterial infections are characterized by a foul smelling feculent exudate Such an odor is caused by other bacteria especially anaerobic streptococci or *Bacteroides* species which are often associated with coliform bacteria in mixed infections

Manifestations *Urinary Tract Infections* Coliform bacilli are the commonest infecting agents in pyelonephritis and cystitis The route by which these organisms reach the urinary tract from the bowel is usually by introduction into the urethra often by catheters or other instruments The frequency of pyelonephritis in young girls is believed to be accounted for by the combination of a short urethra and fecal soiling The pathogenesis clinical manifestations complications and treatment of pyelonephritis are discussed in detail beginning on p 967

Appendicitis and Peritonitis Coliform organisms can nearly always be cultured from the exudate of an appendiceal infection from diverticulitis and from the peritoneal exudate after perforation of a viscus Often they are found in mixed culture with anaerobic streptococci and clostridia It is difficult to assess the role of various bacteria in mixed infections of this type but there is little doubt about the ability of coliforms to infect serous cavities

Biliary Tract Infections Coliform bacilli are the common etiologic agents in obstructive cholangitis So-called Charcot s intermittent fever may be

grenous and eventually slough out to produce ulcers

Destructive gangrenous lesions of the lips and mouth—sometimes called noma—which occasionally occur in chronically ill or malnourished children are apparently associated with spreading infection due to *Pseudomonas*

Treatment The tendency of these infections to occur in damaged ischemic and fibrotic areas or in persons already debilitated makes their therapy difficult Improvement of the patient s general condition may help to eradicate a local infection Urinary infections may subside after surgical removal of obstructive lesions Debridement of devitalized tissues and better drainage of chronic infections are desirable Sulfonamides are partially effective but unfortunately not all strains of *Proteus* and *Pseudomonas* are susceptible to these drugs The discontinuing of ineffective antibiotic therapy permitting reestablishment of normal relationships between the bacterial flora of the body may help to terminate superinfections by these organisms

The selection of a specific chemotherapeutic agent should be made on the basis of sensitivity tests A combination of streptomycin 1 to 2 Gm daily with chloramphenicol or one of the tetracycline drugs is sometimes effective *Proteus* and *Pseudomonas* are irregularly susceptible to neomycin but this drug is very effective against many strains

Most but not all *Pseudomonas* strains are susceptible to polymyxin B This drug in a daily intramuscular dosage of 200 to 500 mg sometimes is lifesaving but when it is used the patient should be observed carefully for renal damage (p 823) Superficial *Pseudomonas* infections (burns external otitis eye) can be treated by local application of polymyxin as a solution or an ointment One per cent acetic acid and nitrofurazone ointment can also be used for surface infections

Many strains of *Proteus* are relatively susceptible to penicillin and successful use of massive doses of this drug (10 to 100 million units daily) has been reported frequently enough that this regimen is well worth trying in life threatening infections Novobiocin is also effective against occasional strain of *Proteus*

119 BACTEROIDES INFECTIONS

Paul B Beeson

Etiology The genus *Bacteroides* includes a group of gram negative non spore bearing anaerobic bacilli Members of this genus are normally found among the flora of the mouth intestinal tract and vagina The species of greatest interest from the standpoint of human infections is *Bacteroides funduliformis* also called *Bacillus fundiliformis* and *Fusiformis necrophorus*

Pathogenesis *Bacteroides* infections probably occur more commonly than is indicated by published case reports Some of them go unrecognized because of the difficulties associated with isolation and identification of anaerobes The usual source of infection is presumed to be the alimentary tract of the host Organisms may be transported to other parts of the body by direct extension or by way of the blood and lymph Members of the genus have been isolated from many different types of infections including tonsillitis otitis media lung abscess empyema arthritis appendicitis peritonitis endometritis pyelonephritis and subacute bacterial endocarditis Usually other intestinal bacteria such as *Escherichia coli* *Clostridium welchii* and anaerobic streptococci are present in addition to the *Bacteroides* From such mixed infections however *Bacteroides* may invade the blood stream and be transported elsewhere producing metastatic infections especially in the lungs joints and liver The septicemic form of *Bacteroides* infection occurs most frequently when thrombophlebitis develops in the vicinity of the primary infection

Manifestations In mixed infections such as otitis media appendical abscess etc the course and symptoms are variable and the role of the *Bacteroides* cannot be evaluated The outcome in

118 *PROTEUS* AND *PSEUDOMONAS* INFECTIONS

Ivan L Bennett Jr

Etiology The *Proteus* genus consists of a group of gram negative motile bacilli which ferment dextrose and sucrose but do not act upon lactose or mannite They split urea producing ammonia The several varieties differ in other biochemical and in serologic reactions One group (X) possesses an antigen similar to that present in certain rickettsiae this probably accounts for the appearance of *Proteus* antibodies (Weil Felix reaction) in certain rickettsial diseases *Proteus vulgaris* *P morganii* and *P rettgeri* are the most common species infecting man

The *Pseudomonas* group of organisms are gram negative motile bacilli which do not ferment carbohydrate and which produce distinctive pigments The clinically important variety is *Ps aeruginosa* often called *Bacillus pyocyaneus* Coloring of exudates by its pigment has caused the organism to be designated as "the bacillus of blue green pus" *Pseudomonas* and *Proteus* bacilli are normal inhabitants of the mouth intestinal tract and skin of human beings *Proteus* and *Pseudomonas* are among the most resistant of common bacteria to antibiotic agents in general use and infection by them is becoming a serious problem in many parts of the world

Pathogenesis *Proteus* and *Pseudomonas* infections are often the result of implantation of the organisms in an already damaged tissue Ordinarily these infections remain limited to one area but particularly in burns or chronic ulcers and sinus tracts the organisms may be disseminated in the blood stream to form metastatic pyogenic infections elsewhere Histologically the lesions of *Pseudomonas* are characterized by thrombosis of small arteries this may produce areas of infarction in which there is little inflammatory reaction or cellular exudation The lesions caused by *Proteus* bacilli show the typical changes of acute inflammation and abscess formation

Because the growth of *Proteus* and *Pseudomonas* is seldom restrained by the administration of antibiotics they often come to dominate the "normal flora" of patients undergoing treatment for some other infection or receiving prophylactic chemotherapy As a result superinfection" (p 829) of the urinary tract middle ear lung etc by these bacilli is becoming an increasingly frequent complication of antibacterial therapy Indeed in many areas nosocomial infection by *Proteus* and *Pseudomonas* is as great a problem as that caused by antibiotic resistant staphylococci

Manifestations *Pseudomonas* and *Proteus* infections can occur in many locations including skin, subcutaneous tissue bone synovial cavities lung kidney meninges ear mastoid cells and paranasal sinuses The most important of these are

Urinary Tract Infections *Pseudomonas* and the *Proteus* bacilli are among the commonest pathogens of the urinary tract It is not unusual for both kinds of organisms to be present at the same time in chronic urinary tract infections or one of them may be present in combination with some other pathogen such as a member of the coliform group See p 967 for a discussion of pyelonephritis

Infections of the Ear, Mastoid, and Paranasal Sinuses *Pseudomonas* and *Proteus* are frequent secondary invaders in infections of these areas They usually occur in combination with gram positive cocci A chronic infection of the external auditory canal due to *Pseudomonas* is sometimes a troublesome ailment causing considerable discomfort and discharge It may lead to thickening of the eardrum and impairment of hearing

Infections of the Eye *Pseudomonas* may become implanted on abrasions of the cornea and may produce an infected ulceration The infection then is likely to spread into the eyeball This is one of the most severe ophthalmic infections and can lead to destruction of the eyeball

Infections of the Skin and Subcutaneous Tissues Chronic ulcerations of the skin such as varicose or decubitus ulcers are very frequently contaminated with *Pseudomonas* and *Proteus* organisms The same is true of burned areas Draining sinuses in chronic osteomyelitis are also susceptible to this type of secondary bacterial infection

Meningitis Primary meningitis caused by these organisms does not occur They may however be introduced into the subarachnoid space in the course of a lumbar puncture or spinal anesthesia or by extension from a focus of infection in the mastoid cells or paranasal sinuses The resulting meningitis is very severe and often fatal

Bacteremia In debilitated persons particularly premature infants and in patients with blood dyscrasias or lymphomas local *Pseudomonas* or *Proteus* infections can lead to bacteremia and a fulminating illness with hectic fever and secondary abscesses which often ends fatally *Pseudomonas* sepsis may be accompanied by a unique skin eruption consisting of vesicular or bullous lesions filled with clear fluid The vesicles rupture a day or two after their appearance the bases then become gan

to those of pneumococci in fact serologic cross reactions occur between certain Friedlander strains and pneumococci Friedlander bacilli have been divided serologically into groups A B C D and E and a heterogeneous group X Most infections in human beings are due to members of group A

Pathogenesis Infections of the urinary and biliary tracts the peritoneal cavity and other serous membranes comprise the bulk of diseases caused by the Friedlander bacilli These are similar in manifestations and pathogenesis to those produced by the coliform organisms discussed on p 878 In the lungs however Friedlander infections take the form of an acute rapidly progressive and often fatal pneumonia or of a chronic lung disease with bronchitis bronchiectasis and cavity formation

Manifestations As already mentioned the majority of infections caused by the Friedlander bacilli are similar to those due to the coliform bacteria Thus Friedlander bacilli may be among the infecting organisms in general peritonitis or they may be the etiologic agents in pyelonephritis or cholangitis Occasionally they cause infections of the middle ear mastoids or paranasal sinuses or meningitis secondary to one of these A significant proportion of all reported cases of Friedlander bacillus meningitis has involved persons with diabetes mellitus Another kind of Friedlander bacillus meningitis is that which complicates traumatic perforation of the skull or spinal canal especially as encountered in war wounds

Acute Pneumonia About 1 per cent of all cases of bacterial pneumonia are caused by Friedlander bacilli The disease is most common in males over forty years of age and is frequent in alcoholic addicts The manifestations are similar to those of pneumococcal pneumonia with sudden onset of chills fever and severe pleuritic pain Patients are more likely to be delirious and prostrated and fever is more often remittent than in pneumococcal pneumonia In about half the cases the sputum is dark brown or red and is so sticky that the patient has difficulty in expelling it from his mouth and lips The pulmonary lesion usually progresses rapidly spreading from lobe to lobe and from one lung to the other within a few days Cyanosis and dyspnea develop rapidly and jaundice vomiting and diarrhea are often present Although x rays may show extensive consolidation in the lungs physical signs may be deceptively few The blood leukocyte count may be elevated but is often low or in the normal range Lung abscess and empyema are frequent complications Previous to the introduction of sulfonamides and streptomycin the fatality rate reported in different clinics varied from 50 to 80 per cent death within 48 hr was not infrequent

Chronic Infection of the Lung This may follow acute Friedlander pneumonia but is also seen in patients who give no history of acute onset The principal manifestations are productive cough weakness and anemia Hemoptysis is not common Chronic empyema or sterile serous effusion is observed in about one fourth the cases Cavity formation frequently occurs and is usually located in the upper lung fields There is very little inflammatory reaction around the cavities so that in roentgenograms they appear to have thin walls A number of patients with chronic Friedlander infection of the lung have had an erroneous diagnosis of pulmonary tuberculosis and have been given sanatorium treatment The course of this disease is quite variable Some cases have been observed for 10 or 20 years with very little change in symptoms and signs whereas others have shown gradual improvement after several months

Diagnosis Diagnosis can be made only by the isolation of Friedlander bacilli A presumptive diagnosis of Friedlander pneumonia can be made on the basis of Gram stain of the sputum this shows numerous short plump gram negative bacilli each surrounded by a clear space because of the capsule In any patient with acute pneumonia whose sputum is found to contain a predominance of gram negative bacilli a presumptive diagnosis of Friedlander infection should be made and appropriate therapy instituted Culture of the sputum on a solid medium shows almost pure growth of Friedlander colonies Certain proof is afforded by isolation of the organisms from the blood pleural exudate or fluid aspirated from the lung

Treatment In view of the age group involved and the frequent association with alcoholism and malnutrition the fatality rate in acute Friedlander pneumonia will doubtless remain fairly high—i e 25 to 50 per cent Specific antiserums have been employed in the treatment of acute Friedlander pneumonia but the results have not been encouraging In vitro Friedlander bacilli are usually susceptible to sulfonamides streptomycin chlortetracycline and chloramphenicol and results of therapy of experimental Friedlander infections with all these agents have been quite satisfactory The best regimen employs streptomycin in large doses (3 to 4 Gm daily) with chloramphenicol or a tetracycline Resistance to streptomycin develops rapidly and if the response is satisfactory the dose can be reduced or it can be discontinued after 3 to 5 days Chloramphenicol or tetracycline should be continued for a minimum of 10 to 14 days

these cases usually depends on the possibility of surgical treatment

Septicemia Following Tonsillar Infection A characteristic disease pattern may be encountered in primary *Bacteroides* infection of the tonsils The patient usually suffers from sore throat for a few days then abruptly becomes extremely ill A hectic type of fever ranging between 101 and 104 F is common and temperature elevations to 106 to 108 F may occur Signs of acute inflammation in the tonsils and pharynx may have subsided but there is usually tenderness in the region of the tonsillar lymph nodes Palpation along the course of one of the internal jugular veins discloses a firm tender cord indicating the presence of a thrombus Septic emboli become lodged in the lungs forming *lung abscesses* and pleural *empyema* may develop Productive cough and pleuritic pain are common at this stage Purulent *arthritis* may develop in one of the large joints e g the elbow shoulder knee or ankle The liver becomes enlarged and tender as a result of acute hepatitis and there may be *icterus* Without appropriate therapy this form of *Bacteroides* infection usually causes death within a few days

Post partum and Postabortal Infection *Bacteriodes* septicemia similar to that which complicates tonsillar infection is occasionally encountered in the post partum or post abortal state Here the primary infection is endometritis with thrombophlebitis in the pelvic veins The manifestations are similar to those just described including septic fever pulmonary symptoms arthritis icterus and hepatitis

Laboratory Findings There is usually a leukocytosis ranging from 12 000 to 25 000 Patients with hepatitis have elevated serum bilirubin and a positive test for bilirubin in the urine but the stools do not become acholic The only method of specific diagnosis is demonstration of *Bacteroides* by cultural methods As already mentioned the organisms are often associated with other bacteria common to the gastrointestinal tract and this makes cultural demonstration technically difficult In bacteremia or metastatic infections however *Bacteroides* can be isolated relatively easily provided that incubation is carried out under anaerobic conditions Thioglycollate broth is suitable The possibility of this type of infection should be considered in appropriate cases and anaerobic cultures made After 1 or 2 weeks it is possible to make a diagnosis by demonstration of a rising titer of agglutinins for stock strains of *Bacteroides* organisms

Treatment Because of the likelihood of mixed infection chemotherapy must be given with a view to the entire picture *Bacteroides* infections have shown little response to sulfonamides or penicillin but there are many reports of favorable outcome following administration of Aureomycin (chlortetracycline) and this appears to be the drug of first choice In view of the tendency to rapid necrosis of tissue with formation of abscesses in which the bacteria are protected from the action of phagocytes chemotherapy alone will not always be successful For this reason a vigilant watch should be kept for signs of abscess or empyema which can be evacuated surgically

Prognosis In mixed local infections the course is variable The fatality rate of septicemic cases formerly was almost 100 per cent but a very considerable reduction has been effected since the introduction of chlortetracycline therapy

120 FRIEDLANDER BACILLUS (KLEBSIELLA) INFECTIONS

Ivan L Bennett Jr

Etiology The Friedlander bacilli (*Klebsiella pneumoniae* or *friedlanderi*) are encapsulated gram negative bacilli found among the normal flora of the mouth and respiratory and intestinal tracts They are closely related to *Acrobacter aerogenes* and cannot be differentiated by biochemical reactions Indeed there is general agreement that separation of the *Aerobacter* genus from *Klebsiella* is not justified although clinical usage will continue to refer to the strains from the respiratory tract as Friedlander bacilli and those from other regions as *Aerobacter* The *Klebsiella* isolated from respiratory infections usually form large mucoid colonies on solid media and are virulent for mice These characteristics however are not invariable enough to differentiate them from intestinal strains The capsular polysaccharides of Friedlander bacilli are similar

to those of pneumococci in fact serologic cross reactions occur between certain Friedlander strains and pneumococci Friedlander bacilli have been divided serologically into groups A B C D and E and a heterogeneous group X Most infections in human beings are due to members of group A

121 TYPHOID FEVER

Paul B Beeson

Definition Typhoid fever is a febrile illness of several weeks duration due to infection with *Salmonella typhosa* and characterized by fever cough headache skin eruption splenomegaly and leukopenia

History Descriptions of typhoidlike illnesses have been given since ancient times The name typhoid fever was first used by French clinicians in the early part of the nineteenth century In 1836 Gerhard of Philadelphia presented the first satisfactory clinical differentiation between typhoid and typhus fevers Between 1855 and 1870 Budd an English practitioner studied the epidemiology of the disease and correctly concluded that the source of contagion was the fecal discharges of affected persons In 1880 Eberth isolated the typhoid bacillus

Typhoid fever has been a prominent disease of military groups and was an important cause of disability and death in wars previous to the First World War Between 1900 and 1910 prophylactic vaccination was developed and the use of this procedure in the First World War reduced the incidence of the disease remarkably As a result of widespread prophylactic vaccination in civilian populations and of improved methods of sanitation typhoid fever is far less common now than 50 years ago The introduction of chloramphenicol therapy in 1948 brought about a drastic change in the duration and prognosis of the disease

Etiology *Salmonella typhosa* is a motile gram negative bacillus which ferments dextrose maltose and mannite without the production of gas and does not ferment lactose or sucrose At least 20 different strains of the organism have been distinguished by testing their susceptibility to lysis by bacteriophages Such typing has been of great assistance in tracing the sources of outbreaks of typhoid fever but is of no particular value to clinicians since there is no distinct difference in the character of diseases produced by the different phage types *S typhosa* has flagellar (H) antigens and somatic (O) antigens which cross react serologically with H and O antigens of certain other *Salmonella*

Epidemiology Human beings are the only known natural hosts of typhoid infection Infection is transferred from the intestinal tract of one person to the mouth of another Great epidemics have resulted from fecal contamination of water or milk supplies but modern methods of sanitation are rendering this mode of spread less common The principal source of infection now is typhoid "carriers —i e persons who have recovered from the disease but continue to harbor the causative organisms Such individuals are particularly dangerous if they are food handlers Transmission by flies is a possibility and is particularly likely to occur where outdoor toilets are used Contamination of water supplies from improperly constructed toilets can also occur Epidemics have resulted from the eating of shellfish caught in areas of sewage disposal Formerly typhoid fever was especially prevalent in the summer and early fall This may have been due to such factors as better bacterial growth in warm weather fly season and vacation travel At present however there is no marked seasonal variation cases are acquired from carriers sporadically throughout the year

Pathogenesis There can be no question that the portal of infection is the gastrointestinal tract The point at which bacteria actually enter the tissues is not so certain however It is commonly stated that the bacilli are first taken up by the lymphoid tissue of the intestinal wall especially the Peyer s patches and that drainage from there involves the mesenteric lymph nodes It has been proposed by some workers on the other hand that invasion of the tissues may occur in the pharynx and tonsils Whatever the primary point of invasion the next significant factor in the development of typhoid fever is the presence of bacilli in the circulating blood This is undoubtedly due to a constant feeding of organisms into the blood from some focus such as the mesenteric lymph nodes The bacteremia permits secondary infection of the other areas liver spleen, bone marrow and other lymph nodes At the end of the first week of infection antibodies appear in the blood and the bacteremia usually ceases From this stage onward the infection which has been established in the biliary tract is particularly important since it furnishes a flood of infected material to the upper part of the small intestine This probably is responsible for the heavy

involvement of the Peyer s patches during the sec ond and third weeks of the disease and for the pres ence of organisms in the fecal discharges

The gross autopsy findings in patients dying of typhoid fever are those of inflammatory involve ment of lymphoid tissues especially in the wall of the intestine and in the mesenteric lymph nodes and the spleen The spleen is enlarged as is the liver The Peyer s patches become swollen and may undergo necrosis leaving oval shaped ulcers these are most numerous in the terminal ileum but may extend as high as the jejunum or as low as the appendix and cecum They are responsible for the most serious complications of typhoid fever per foration and hemorrhage

The common denominator underlying typhoid lesions wherever encountered consists in a marked proliferation of large mononuclear cells derived from the reticuloendothelial system This prolifera tion encroaches on blood vessels and leads to necrosis of tissue Microscopic examination of the intestinal lesions reveals few bacilli in the extra cellular spaces most of them appear to be located within macrophages Goodpasture has reported that typhoid bacilli can also be found within plasma cells This phagocytosis may serve the parasite bet ter than the host since intracellular existence of the organisms may protect them from such agents as antibodies and drugs This may explain why the disease seems to continue without observable clin ical change after the appearance of antibodies in the blood and why signs of clinical improvement do not become manifest until 2 or 3 days after beginning chloramphenicol therapy

Because the most prominent inflammatory changes are found in the intestine there is a tendency to regard typhoid fever as a primary enteric infection A consideration of the observed facts however leads to the conclusion that the in testinal infection is largely secondary to the biliary tract infection which in turn is sequel to the initial bacteremia The fact that organisms are constantly present in the blood during the early period while they do not appear in the stools until the second or third week, speaks for an important extraintestinal focus of the infection

Manifestations The incubation period of typhoid fever in sporadic cases usually cannot be deter mined but in epidemics which have followed a single exposure the incubation periods showed con siderable variation averaging 10 to 12 days

The clinical manifestations of typhoid fever are exceedingly variable Some persons can be infected without any disability whatever some suffer only a brief febrile illness In others the disease takes the form of an overwhelming infection leading to death within a few days In the majority of cases recovery occurs after an illness of several weeks The de scription to follow will deal chiefly with cases of average severity but it should be emphasized that the clinician must always have in mind the great variability of typhoid fever

The first symptoms are usually abdominal dis comfort malaise feverishness anorexia weakness headache and cough and their onset is so insidi ous that the patient does not go to bed for several days The fever is remittent in type gradually in creasing in height until about the tenth day when it may fluctuate between 103 and 105 F This con tinues for the next 10 days or 2 weeks then the daily remissions begin to be greater and there is a gradual fall over a period of several days with fever terminating after a total period of about 30 days Chills may occur during the early part of the in fection occasionally the first sign of illnes is a chill Nosebleeds may be troublesome Bronchitis is prominent and typhoid is frequently mistaken for some form of primary pulmonary infection in the early stage Scattered fine and medium moist rales may be heard at the lung bases x ray of the chest may occasionally reveal one or more small areas of pulmonary consolidation The headache is of great severity and may be the chief complaint Curi ously herpes simplex is very rare in typhoid fever The patient is likely to suffer from abdominal dis tention and colicky pain There may be either diar rhea or constipation the latter being more frequent at the onset At the height of the disease diarrhea may supervene and numerous pea soup stools may be passed daily When the fever has reached its peak the patient may be apathetic and drowsy or he may show delirium The appearance is that of severe toxemia The typhoid patient seldom seems alert Muscular twitching and picking at the bedclothes may be noted in patients who have had prolonged high fever

The eruption usually appears during the second week The lesions which are called "rose spots" are found most often on the anterior surface of the trunk between the level of the nipples and the um bilicus They are small rose red spots 2 to 4 mm in diameter and usually have a small central peak which is palpable Their color fades completely on pressure They are not numerous usually only 6 to 12 may be seen at a time They tend to appear in crops and to disappear without leaving any discol oration When extensive they may also be present on the proximal parts of the extremities but are seldom seen on the face and practically never on the palms or soles

The spleen becomes palpable by the end of the first week in the majority of cases It is soft and may be missed if the examiner palpates too deeply It rarely extends more than 2 or 3 cm below the costal margin and recedes by the time the fever begins to subside

During the first week or two of typhoid fever the pulse rate is usually comparatively slow in relation to the fever this is sometimes of assistance in diagnosis After the third week however the pulse rate is proportional to the temperature A dicrotic pulse is often present but this is not particularly helpful in diagnosis

With the beginning of the subsidence of the fever there is gradual improvement in symptoms and a return of the patient s appetite Usually however a marked weakness persists for many days after the temperature has returned to normal

Relapse is not uncommon in typhoid Some reports indicate that the frequency is as high as 10 per cent The clinical features are similar to although milder than those of the initial illness There may be a recurrence of the bacteremia and even of the skin eruption Fatalities are uncommon during relapses

Complications *Hemorrhage from the bowel* is the most important complication of typhoid fever Gross bleeding occurs in about 20 per cent of cases This is usually during the third week of the disease at the time when the intestinal ulcerations have reached their greatest extent Severe hemorrhage is accompanied by the signs and symptoms of acute blood loss—i e rapid weak pulse low blood pressure sweating pallor and drowsiness—and by the appearance of gross blood in the stools One sign occasionally of value as an indication of massive hemorrhage is rapid fall in body temperature a decrease of 5 or 6 F in the course of a few hours

Perforation of the intestine is a very dangerous complication and one which accounts for many of the deaths in typhoid fever Fortunately it is far less common than hemorrhage (1 to 2 per cent of cases) Perforation takes place at the site of an ulcer usually in the terminal ileum but occasionally in the appendix or in the proximal part of the colon Occasionally there are multiple perforations The clinical manifestations are pain usually in the right lower quadrant followed by rigidity and diminished peristalsis Signs of free air in the peritoneal cavity may be detected The pulse rate may increase there is usually a rise in leukocyte count and the temperature may fall Diagnosis of perforation may be very difficult because of pre existing abdominal distention tenderness and pain Frequent examinations throughout the course of the disease by the attending physician assist him in recognizing and evaluating the changes which occur with perforation

Bacterial pneumonia occasionally complicates typhoid fever If suspected this can be verified by physical examination and x ray and by appropriate bacteriologic studies Many other complications of typhoid fever can be mentioned they include the various infections likely to arise in a severely ill patient such as *parotitis sinusitis conjunctivitis* etc *Thromboembolic disease* may occur *Meningitis* and *arthritis* due to *S typhosa* are rare complications

Three late sequelae of this disease deserve mention *Periostitis* may develop months or even years after the original illness It may involve almost any of the long bones or the spine The lesion is as the name implies on the outside of the bone clinically there is a tendency to abscess formation with periodic rupture through the skin and healing The second complication is *gallbladder disease* Signs of cholecystitis occasionally are noted during the acute illness Years later the subject may suffer from cholecystitis and cholelithiasis Gallbladder stones containing live typhoid bacilli are said to have been removed 20 or 30 years after the original attack of typhoid fever Finally a *chronic pyelonephritis* or *pyonephrosis* due to *S typhosa* may develop

The Carrier State Approximately 2 or 3 per cent of patients with typhoid fever can be expected to become typhoid carriers i e to continue excreting the organisms in the feces for months or years after clinical recovery In most instances the carrier state is due to persistence of infection in the biliary tract and cholecystectomy is usually effective in eradicating the condition Urinary carriers are occasionally encountered but they constitute a much less serious problem than intestinal carriers

Laboratory Findings The *leukocyte count* during the first week or two is usually in the low normal range (i e 5 000 to 8 000) during the third and fourth weeks it may become even lower (3 000 to 6 000) During convalescence there is a rise The *red blood corpuscle count* falls progressively during the course of the disease and often reaches a level of 3 000 000 to 3 500 000 in the third and fourth weeks Acute hemolytic crises have been observed The *urine* contains some albumin during the febrile stage but is otherwise not remarkable Tests for *occult blood in the feces* are usually positive from the second to the fourth week of the disease

Culture of the blood is positive for *S typhosa* during the first week of the disease in about 90 per cent of cases After that time the likelihood of a positive blood culture decreases rapidly *Culture of the feces* is rarely positive for *S typhosa* before the tenth day of the disease The incidence then increases rapidly up to the fourth week of illness the organisms can be recovered from the feces in at least 90 per cent of cases if good bacteriologic technique is employed Bismuth sulfite agar in conjunction with selenite F or tetrathionate enrichment medium gives excellent results *Culture of the urine* is positive during the third and fourth weeks in about 20 per cent of cases of typhoid fever

Examination of the blood for *specific agglutinins* (*Widal test*) usually gives a positive result at the end of 7 to 10 days of illness The titer of agglutinins rises during the next 10 days reaching a peak about the third or fourth week of illness The titer then falls gradually during the succeeding months There has been much discussion of the relative values of H and O agglutination tests in diagnosis The titer of H antibody is usually higher than that for O and the H sometimes appears a few days earlier No definite figure of certain diagnostic significance can be given As with all serologic tests a rising titer during the course of the illness is more significant than any individual figure In general titers higher than 1 160 with both antigens are probably significant and the O antigen is more specific than the H In about 10 per cent of cases the Widal test never reaches diagnostic" titers Previous immunization with typhoid vaccine has to be taken into consideration in evaluating the results of Widal tests A person who has received an immunization during the preceding 6 months would be likely to show specific agglutinins in his serum Furthermore an anamnestic response to any infection may cause the reappearance of antityphoid antibodies in the serum of a previously inoculated person

Differential Diagnosis The sporadic cases of typhoid fever seen nowadays nearly always present diagnostic problems and positive differentiation often has to wait for laboratory tests Nevertheless positive diagnosis of typhoid fever can be made by means of laboratory tests which are generally available i e culture of blood and feces and the agglutination (Widal) test Differentiation of typhoid fever from other diseases which resemble it such as the ones listed below depends in most cases upon the establishment of a *positive diagnosis of typhoid fever* Repeated negative cultures and agglutination tests should direct attention away from typhoid since it would be a rare experience to encounter typhoid fever with negative Widal test and negative cultures of blood feces and urine The following diseases should receive particular consideration

Typhus Fever The onset is usually sudden with chill followed by sustained high fever The rash is more profuse and the individual lesions are not palpable The Weil Felix test is positive

Atypical Pneumonia The insidious onset with respiratory symptoms resembles typhoid but abdominal discomfort and gastrointestinal symptoms are lacking X ray reveals a sizable area of pulmonary consolidation which is rare in early typhoid Cold agglutinins if present will bear out the diagnosis

Brucellosis The clinical picture may be indistinguishable except for absence of rose spots and the fact that the pulse rate is usually elevated in proportion to the fever Blood and feces cultures and agglutination tests will differentiate

Tularemia Rarely this disease appears in the so called typhoidal form History of contact with rabbits or squirrels or tick bite should suggest tularemia There is usually a leukocytosis The agglutination test is nearly always positive by the end of the second week Rapid improvement under streptomycin or chlortetracycline treatment points to this disease

Miliary Tuberculosis The chest x ray may not show lesions until late in the disease and occasionally is negative throughout Spinal fluid examination may be of assistance

Psittacosis The clinical resemblance to typhoid fever may be remarkable including insidious onset with cough then high remittent fever an eruption with lesions like "rose spots and splenomegaly The pneumonia is however more conspicuous than the pulmonic infection of typhoid Diagnosis of psittacosis can be made by serologic test but may not be possible until comparatively late in the course of the disease

Hodgkin s Disease When the main lymph node involvement is in the abdomen this condition may mimic typhoid fever Here again repeated negative cultures and agglutinations tests should eliminate typhoid fever from consideration The finding of large lymph nodes in the thorax or other areas will eventually lead to a correct diagnosis

Treatment Precautions should be taken to prevent spread of infection from the patient to others Attendants should wear gowns to avoid contamination of clothing and should wash their hands thoroughly with soap and water after contact with the patient or his bedclothes The principal sources of danger are the patient s dejecta The best method of disposal in localities with properly constructed sewage systems is by way of flush toilets Chemical disinfection of urine is not difficult but disinfection of fecal material is almost impossible Bedpans urinals eating utensils bedclothes and bedding should be sterilized by boiling

It has always been maintained that nursing care and general supportive treatment are of paramount importance in the treatment of typhoid fever and the disease has been used as the prototype for discussions of care of patients with febrile illnesses While these measures still deserve consideration their relative importance has shrunk substantially because of the introduction of chloramphenicol therapy

Chloramphenicol is a highly effective specific drug for the treatment of typhoid fever Bacteremia ceases within a few hours after the first dose During the next two days the patient begins to feel somewhat better although the fever shows little change

During the third or fourth day there is dramatic improvement with fall in temperature disappearance of symptoms and fading of the skin eruption The patient is now on the road to recovery

A dose of 2 Gm chloramphenicol per day administered at 6 or 8 hour intervals is adequate Treatment can be discontinued at the end of 7 days in most cases but relapse will occur occasionally necessitating a second course Relapse can be prevented in the great majority of cases by continuing chloramphenicol for 3 weeks In a few instances hemorrhage and perforation have occurred several days after apparent favorable response to chloramphenicol consequently it is desirable to keep the patient under observation for at least 2 weeks The ameliorative effect of chloramphenicol can be rendered even more spectacular by the adjuvant administration of cortisone 100 to 200 mg daily This appears to be safe and to bring about defervescence of fever and subsidence of the toxic symptoms on the first instead of the third or fourth day of treatment Cortisone should probably be discontinued after 3 or 4 days therapy with chloramphenicol being maintained for the full period as already outlined

In the event of massive intestinal bleeding the patient must be given blood transfusions Intestinal perforation has always been regarded as indication for incision and drainage and this is probably still the correct view although the question may be raised whether better results might follow conservative management with administration of large doses of penicillin and chloramphenicol

During convalescence culture of the feces and urine should be done at intervals and the patient should not be discharged until three consecutive negative cultures have been obtained In the event that cultures remain positive long after clinical recovery the patient should be instructed about the danger and health authorities should be notified before his release from the hospital Cholecystectomy is not justified until the patient has continued to excrete typhoid bacilli for at least 1 year since the carrier state may cease spontaneously during that period of time The operation will successfully eradicate the carrier state in about 90 per cent of cases Chloramphenicol therapy of typhoid carriers has not been effective Some success has been obtained by treating biliary carriers with large doses of penicillin i e 10 million units daily for 6 to 10 days This should be given a trial before resorting to surgery

Immunization Vaccination against this disease is practiced in all parts of the world and there is no question that it confers some protection although there have been numerous instances of typhoid fever among vaccinated persons who had ingested heavily contaminated food or water Vaccines contain chemically killed typhoid bacilli in suspensions of approximately one billion cells per milliliter The usual dosage schedule is 0 5 to 1 0 ml subcutaneously administered on three occasions at weekly intervals

Prognosis The fatality rate in typhoid fever before chloramphenicol was 8 to 12 per cent the greatest incidence of deaths being in young infants and in the aged Massive hemorrhage and intestinal perforation account for a considerable proportion of deaths With early institution of chloramphenicol therapy the fatality rate should not exceed 1 or 2 per cent except where the disease occurs in previously debilitated and malnourished population groups

122 OTHER *SALMONELLA* INFECTIONS

Edward W Hook and
Ivan L Bennett Jr

Definition Although there is variation in the pathogenicity of the many different members of the *Salmonella* genus almost all are capable of producing human disease The infections in man are *acute gastroenteritis or food poisoning enteric or paratyphoid fever* which resembles typhoid clinically but is usually a milder illness *bacteremia* and a multitude of *localized infections* ranging from osteomyelitis to endocarditis

Etiology and Epidemiology The *Salmonella* are gram negative bacilli that inhabit the intestines of man and many animals and birds including mice rats cats dogs pigs chickens and ducks The organisms are motile ferment dextrose maltose and mannite with production of gas and do not utilize lactose or sucrose Accurate identification is technically complex and can be carried out only in a few typing centers but is very important for epidemiologic studies It is sometimes difficult or impossible to differentiate *Salmonella* from *Para*

colon bacilli (see p 868) in the ordinary clinical laboratory *Salmonella typhosa* (see p 884) and *S pullorum* differ from other species in failing to produce gas *Salmonella gallinarum* and *S pullorum* are nonmotile Several hundred species of *Salmonella* have been differentiated on the basis of their somatic (O) and flagellar (H) antigenic structure With rare exceptions human infection occurs by the oral route The meat of infected animals eggs of infected fowl (spray-dried powdered egg preparations often contain *Salmonella*) and food milk or water contaminated by excreta of man or animals are common sources Large epidemics of gastroenteritis are common and are not usually as explosive as those produced by staphylococcal enterotoxin (p 845) In 1953 an outbreak of more than 8 000 cases of *S typhimurium* infection in Stockholm was traced to contaminated meat from a slaughterhouse The most frequent causes of human infection in the United States are *S typhimurium S newport S oranienburg S montevideo* and *S choleraesuis* (*S suipestifer*) in that order (Saphra and Wassermann)

Human carriers of *Salmonella* are not rare many give no history of symptomatic infection The coliform bacteria of the intestinal microflora apparently exert a protective action by suppressing multiplication of *Salmonella* if the number ingested is small This suggestion is based upon the demonstration that elimination of intestinal saprophytes by giving antibiotics increases susceptibility of mice to infection with *S typhimurium* 100 000 fold *Salmonella* enteritis has been reported to complicate the administration of broad spectrum antibiotics to man (see Staphylococcal Enterocolitis p 1475) and patients convalescent from gastrointestinal surgery are known to be unusually susceptible to salmonellosis

The incidence of infection due to *Salmonella* is greatest during the summer months *Salmonella choleraesuis* infections do not follow this seasonal distribution and occur at a fairly constant rate throughout the year

Pathogenesis Multiplication of ingested organisms in the intestinal tract is followed by symptoms of food poisoning which in the majority of instances subside after a few days The intestinal irritation and inflammation are probably produced by true infection of the mucosa and penetration of the intestinal wall with resulting transient bacteremia or more serious systemic illness occurs in a few patients The invasive potential of the bacteria and the resistance of the infected host determine the course of events after *Salmonella* have gained access to the gastrointestinal tract For example about 50 per cent of *S choleraesuis* infections are accompanied by bacteremia and the mortality rate is about 20 per cent The infrequent occurrence of gastroenteritis and a carrier state due to *S choleraesuis* also reflects the invasiveness of this organism Bacteremia is unusual in infections produced by most other species the mortality is much lower and the carrier rate is higher

Patients with debilitating disorders of many types are unusually susceptible to severe *Salmonella* infections Another disease is present in about one half the patients who develop sporadic infection Deaths from bartonellosis or Oroya fever (p 915) are often the result of *Salmonella* bacteremia Invasion of the blood stream by these bacteria also occurs in viral hepatitis thalassemia leukemia and cirrhosis of the liver In these last two conditions *Salmonella* bacteremia is probably a reflection of a general increase in susceptibility to infection by gram negative enteric bacteria Relapsing fever (p 1017) is sometimes complicated by salmonellosis and patients with sickle cell anemia are peculiarly susceptible to *Salmonella* osteomyelitis Patients with tumors of various types may develop *Salmonella* bacteremia and in several reported instances the neoplasm itself has been the seat of localized suppuration

With the development of systemic infection there may be histologic changes similar to those of typhoid fever (p 884) or multiple foci of suppuration in bone joints endocardium pleura meninges etc

Clinical Manifestations *Salmonella Food Poisoning* Gastroenteritis often occurs in epidemics among individuals who have partaken of the same contaminated food although sporadic cases are not infrequent After an incubation period of 8 to 48 hr there is sudden onset of colicky abdominal pain and loose watery diarrhea occasionally with mucus or blood Nausea and vomiting are frequent but are rarely severe or protracted Fever of 101 to 102 F is common and there may be an initial chill Symptoms usually subside promptly within 2 to 5 days and recovery is uneventful Fatalities rarely exceed 1 or 2 per cent of the affected population and are limited almost entirely to infants the aged and debilitated patients

The causative organisms can often be isolated from the suspected food and from feces during the acute illness Stool cultures usually become negative for *Salmonella* within a few days but it is not unusual for patients to continue to excrete organisms for weeks or months The blood leukocyte count is usually normal

Enteric or Paratyphoid Fever Certain species can produce an illness which is clinically indistinguishable from typhoid fever i e a prolonged febrile illness with rose spots splenomegaly leukopenia gastrointestinal symptoms and positive blood and stool cultures (see p 884) The organisms most likely to produce this picture are *S paratyphi*

A S paratyphi B (*S schottmuelleri*) and *S choleraesuis* (*S suipestifer*) Occasionally a typical attack of food poisoning is followed in a few days by paratyphoid fever Generally paratyphoid fevers tend to be milder than *S typhosa* infections but differentiation on clinical grounds alone is not possible in the individual case Recovery may be followed by continued excretion of the causative organism in the stools for several months although the carrier state is less frequent and less prolonged than in typhoid

Bacteremia *Salmonella choleraesuis* (*S suipestifer*) is the species most likely to produce bacteremia but prolonged illness with positive blood cultures has also resulted from infection with many other types particularly in patients with another debilitating illness Although symptoms of gastroenteritis can precede bacteremia they are usually lacking and most cases arise sporadically In many instances the only manifestations are prolonged fever sometimes low grade but often spiking and accompanied by repeated rigors sweats aching anorexia and weight loss The characteristic features of typhoid and paratyphoid fever such as rose spots persistent leukopenia and sustained fever are absent Stool cultures are usually negative Discharge of organisms into the blood stream is intermittent (in contrast to the constant bacteremia of typhoid paratyphoid) and repeated blood cultures are often required to demonstrate the causative organism At some time early or late in the course of the illness localizing signs of infection appear in one fourth the cases Pulmonary infection in the form of bronchopneumonia or abscess pleurisy empyema pericarditis endocarditis pyelonephritis meningitis osteomyelitis and arthritis are relatively common The blood leukocyte count is usually normal but with the development of focal lesions polymorphonuclear leukocytosis as high as 20 000 to 25 000 per cubic millimeter occurs *Salmonella* bacteremia can be a very puzzling disorder especially before localization takes place and should be considered in cases of fever of unknown origin

Local Pyogenic Infections In addition to the suppurative lesions already mentioned *Salmonella* organisms can produce abscesses in almost any anatomic site These can occur independently of previous symptoms of gastroenteritis or other illness or as complications of bacteremias There is nothing characteristic about the suppurative lesions and the correct etiologic diagnosis is rarely made on the basis of clinical findings alone Meningeal localization of *Salmonella* infection is common in newborns and infants and occasional small outbreaks of *Salmonella* infection in nurseries have consisted entirely of cases of meningitis

Diagnosis Febrile gastroenteritis produced by presumed viral agents (see p 1105) and shigellosis can be distinguished from *Salmonella* food poisoning only by appropriate stool cultures in most instances especially in sporadic cases The bacteriologic methods are described on p 892 Staphylococcal food poisoning is usually an afebrile disease and vomiting is a more prominent feature than in most *Salmonella* infections Many toxic agents and drugs can produce diarrhea nausea and abdominal pain but fever is rarely a feature of these disorders and the diagnosis depends upon history of exposure or ingestion

The diagnosis of paratyphoid fever or *Salmonella* bacteremia depends upon isolation of the causative organism Agglutination tests with acute and convalescent serum as performed in the usual clinical laboratory are usually not very helpful

Treatment The treatment of *Salmonella* food poisoning is supportive Dehydration should be corrected by parenteral administration of fluids and electrolytes The abdominal cramps and diarrhea can be alleviated by small doses of morphine or paregoric and are frequently much improved if the patient takes nothing by mouth for 8 to 12 hr There is no evidence that antimicrobial drugs modify the course of the disease

Chloramphenicol is the antibiotic of choice in systemic infections the dosage being 2 to 4 Gm daily Its effectiveness is variable and unpredictable The tetracycline derivatives have sometimes appeared to exert a beneficial effect but streptomycin polymyxin neomycin and the sulfonamides are generally ineffective Occasional dramatic results have been obtained with massive doses of penicillin (40 to 100 million units daily) and this should be tried in any patient who is seriously ill with endocarditis meningitis etc

Antibiotic therapy is usually ineffective in terminating the carrier state in persons continuing to excrete *Salmonella* months after an acute illness Cholecystectomy is often effective in eradicating the carrier state in patients with gallbladder disease

Surgically accessible suppurative lesions should be drained

123 BACILLARY DYSENTERY (*SHIGELLA* INFECTIONS)

Ivan L Bennett Jr

Definition With rare exceptions human infection by bacteria of the genus *Shigella* (often called the dysentery bacilli) is limited to the intestinal tract and is characterized by fever abdominal pain and diarrhea In clinical practice this disease is usually called bacillary dysentery a preferable term is shigellosis but this has not achieved wide usage

Etiology The *Shigella* are short nonmotile gram negative bacilli which either fail to ferment lactose or do so only slowly Their biochemical characteristics are sufficiently constant to serve as a reliable guide in identification although definitive typing into species is dependent upon complex antigenic analysis There is considerable confusion about the nomenclature of this genus The official classification (Kauffmann) consists of group A the *Shigella* unable to ferment mannite and groups B C and D the mannite fermenters There are several numerically designated types in each group The organisms are still widely referred to by earlier terminology The most important species from a clinical viewpoint are *Shigella shigae* (*Sh dysenteriae* the Shiga Kruse bacillus) *Sh flexneri* (*Sh paradysenteriae*) *Sh boydii* and *Sh sonnei* Two species *Sh alkalescens* and *Sh dispar* are almost never associated with outbreaks of diarrheal disease and are thought by many to be better classified as saprophytic coliforms than as enteric pathogens Isolation of either from the stool of a patient with diarrhea does not establish a diagnosis of bacillary dysentery

Shigella shigae contains a substance that is neurotoxic for animals and resembles a true exotoxin Evidence for a significant role of this toxin in human disease is lacking All *Shigella* possess endotoxins similar to those of gram negative bacilli in general but the manifestations of bacillary dysentery cannot be attributed to these substances either

Epidemiology In contrast to the *Salmonella* group which is widespread throughout the animal kingdom *Shigella* live primarily in the gut of man although monkeys and rarely dogs may excrete the organisms The convalescent or asymptomatic carrier is the principal reservoir of the disease The only important route of spread is fecal oral transmission is indirect by means of food utensils towels etc Watt and Hardy have conducted cultural surveys in this country and have found carrier rates ranging from 10 per cent of the population in certain parts of New Mexico to 0 1 per cent in New York City Studies such as that of Philbrook have shown that excretion of *Shigella* by carriers is so intermittent that practically speaking their detection and treatment on any large scale is impossible

In regions of the world where sanitation is poor and under conditions such as mobilization of troops in the field epidemics of dysentery are common Outbreaks are rarely explosive but develop over a period of several weeks The ability of some *Shigella* strains to survive in sea water for 3 days was shown by Cheever to be responsible for ship to ship spread of dysentery among naval personnel Flies can transmit the infection by mechanical contamination and in warm climates where sewerage is poor the number of cases of dysentery parallels the fly count In such circumstances fly control becomes an important measure in prevention

In the civilized countries of the world large outbreaks of *Shigella* are now rare with the exception of so called asylum dysentery occurring in mental institutions and orphanages where there are close contact and unusual opportunity for fecal soiling among the feebleminded or youthful inmates

Pathogenesis The monkey is the only laboratory animal in which *Shigella* dysentery can be produced with regularity In volunteer studies it has required the ingestion of surprisingly large numbers of bacilli to establish infection in man

Multiplication of ingested bacilli in the intestinal tract is followed by a diffuse enteritis The rectum and sigmoid are almost always involved and in severe cases the entire colon and terminal ileum may be diseased The infection remains localized in the intestinal wall there being no tendency to invasion of the blood stream or biliary tract as in typhoid fever or other *Salmonella* infections The lumen of the affected segments is covered by a fibrinous exudate containing large numbers of neutrophils and as necrosis of mucosal cells develops superficial ulcerations that bleed easily appear In severe case the ulcers enlarge and coalesce until only a few scattered patches of intact mucosa remain on the raw and inflamed surface While the inflammatory process sometimes involves the submucosa and muscularis with resulting edema and thickening of the intestinal wall perforation is very rare The systemic effects of the disease result al

most entirely from losses of fluid and electrolytes with the diarrhea

Even in untreated cases spontaneous recovery usually occurs within a few days with rapid restoration of the intestinal mucosa to normal The mechanism of this is not known It is clearly unrelated to antibody formation and the suggestion that bacteriophage may be involved is entirely without evidence

Relapses are sometimes seen and second attacks are not infrequent These are again unrelated to serum antibody levels Residency in endemic areas in the tropics is well known to lead to resistance to clinically apparent attacks of bacillary dysentery The basis for this seasoning is also unknown

Manifestations The incubation period is usually 24 to 48 hr Colicky abdominal pain is followed within an hour by profuse diarrhea Fever up to 104 F occasionally with chills occurs and nausea and vomiting headache and malaise develop rapidly Stools are watery greenish and irritating and contain shreds of mucus and often flecks of blood In a few patients there may be profuse bleeding Tenesmus and straining are prominent accompaniments of the diarrhea Depending upon fluid losses the patient may become profoundly dehydrated and circulatory collapse can occur especially in elderly or debilitated patients There is generalized abdominal tenderness without rigidity or localizing signs Rarely the spleen is palpable Sigmoidoscopic examination reveals diffuse mucosal inflammation often with multiple ulcerations The ulcers are not so large or so sharply demarcated as those of amebic colitis and in amebiasis the intervening mucosa is usually uninflamed

Spontaneous recovery within 2 to 7 days is usual with relapses in about 10 per cent of the cases unless chemotherapy is given Children under two years of age and elderly individuals are usually more severely ill and the mortality rate is highest in these groups

Shigella shigae produces the severest infections mortality rates of 25 to 50 per cent have been recorded in epidemics produced by this species which is fortunately very uncommon in the United States

Chronic bacillary dysentery is virtually unheard of in this country but it is said to occur in the tropics especially after Shiga infections The role of reinfection in such cases has not been evaluated and many of these cases probably represent amebic infections Patients may continue to shed *Shigella* after convalescence the true incidence of the carrier state is probably higher than has been realized in view of the intermittency with which positive cultures are obtained in carefully controlled follow up studies

Complications include acute *arthritis* usually involving a single large weight bearing joint during convalescence Joint fluid is sterile This complication is unusual in patients given chemotherapy and is most likely to follow infections with *Sh shigae* which have a protracted course *Reiter s syndrome* the triad of arthritis conjunctivitis and urethritis is thought by some to be a sequel of *Shigella* infections This is discussed on p 1154

There is no convincing evidence to support the assertion that bacillary dysentery and chronic ulcerative colitis are etiologically related

A few instances of perforation of the colon have been reported *Shigella* organisms have been isolated from abscesses but this is very uncommon *Shigella alkalescens* has been reported as the causative agent in acute pyelonephritis and has been isolated from the blood in rare instances many of these infections have been in children

Laboratory Findings The blood leukocyte count in bacillary dysentery is normal Changes in erythrocytes and urine are secondary to dehydration Microscopic examination of the stool reveals shreds of mucus erythrocytes and polymorphonuclear leukocytes Pus cells are not characteristic of the stools in amebiasis although they occur in *Salmonella* enteritis

The causative organism can be isolated in most cases from stool cultures using feces emulsified in saline solution A better technique for obtaining cultures is to swab the rectal mucosa Preliminary incubation in a medium such as selenite F is helpful but cultures can be streaked directly onto SS or desoxycholate citrate agar plates A positive diagnosis should be obtained in at least 80 per cent of cases of bacillary dysentery

Serologic changes are not diagnostic because of the many cross reactions within the *Shigella* group and with other enteric bacilli

Diagnosis *Shigella* infection should be suspected in every febrile diarrheal illness especially if it occurs in epidemic form Outbreaks of staphylococcal food poisoning or *Salmonella* gastroenteritis are usually more explosive than those of bacillary dysentery Staphylococcal food poisoning is usually an afebrile disease in which nausea and vomiting are very severe *Salmonella* infection can be differentiated with certainty only by bacteriologic studies Amebic colitis is rarely epidemic its onset is not usually abrupt and prostrating and motile amebas are found in the stools Diarrheas of viral origin are usually unaccompanied by mucus and blood in the stools but this is not invariable (see p 1105)

In children the onset of otitis tonsillitis pneumonia poliomyelitis or osteomyelitis is often accompanied by diarrhea but careful clinical examination usually clarifies the situation

Treatment The sulfonamides are highly effective in *Shigella* infections Sulfadiazine 4 Gm initially

followed by 1 Gm every 4 to 6 hr is adequate Fluid intake is very important in patients with diarrhea given sulfonamides Poorly absorbed drugs such as Sulfasuxidine (3 to 4 Gm every 6 hr) are effective but offer no advantage Treatment should be continued for 7 to 10 days Occasional strains of *Shigella* are resistant to sulfonamides Oral chloramphenicol and tetracyclines are effective in a dosage of 1 to 2 Gm daily Streptomycin and polymyxin B have been used in a dosage of 0 5 to 1 0 Gm daily by the oral route with good success

Fluid replacement sufficient to maintain urine output of 1 000 ml per day is important intravenous infusion is sometimes needed and rarely blood transfusion is required because of excessive blood loss

The diet is unimportant In many patients symptoms are aggravated by ingestion of food or fluid and it is advisable to rely on the parenteral route during the acute phase of the disease Paregoric codeine or morphine often alleviates abdominal cramping diarrhea and tenesmus

Chloromycetin is more effective in eliminating *Shigella* from the stools of chronic carriers than are the sulfonamides

Prevention The most important prophylactic measures are the maintenance of proper sanitation and adequate sewage disposal The detection and elimination of carriers is difficult and rarely practicable Various vaccines oral and parenteral have been used Although the results of limited trials have been reported with enthusiasm more extensive experience offers no indication that parenteral vaccine exerts a significant protective effect The wide range of potentially pathogenic species necessitating a polyvalent vaccine is another discouraging aspect of this approach to prophylaxis

124 CHOLERA

W Elizabeth Gambrell

Definition Cholera is an acute infectious disease caused by a spirillum the *Vibrio comma* localized in the gastrointestinal tract and characterized by diarrhea vomiting and extreme dehydration

Etiology The causative agent is a comma shaped gram negative bacillus with a single polar flagellum It is actively motile aerobic and easily stained by the acridine dyes Antigenically there is a single flagellar antigen the H antigen one common somatic or O antigen and several secondary somatic antigens by which different serologic strains can be distinguished

Epidemiology The original home of cholera is the delta of the Ganges where it has occurred year after year for centuries It has not been a problem in the United States since the epidemic of 1873 but it is still endemic and often epidemic in India China and other countries of the Orient The great epidemics of the nineteenth century spread to all but the coldest parts of the world The potential distribution of cholera is practically world wide and in the Far East the danger of epidemics is always present

The organism may persist in nature for a short period of time but is usually spread from person to person by patients in the incubation or convalescent stages or by those with subclinical infections True carriers probably do not exist but convalescent patients may remain carriers for a short period of time The organisms are transmitted in food drink or other material contaminated by infected feces Contaminated water and flies are the principal vehicles Diet which is largely vegetarian and previous enteric infections predispose individuals to cholera The disease cannot spread however when sanitary facilities are in efficient operation

Manifestations There is great difference in the susceptibility of individuals who contract the disease some show acute reactions while others have mild attacks characterized by only slight malaise and diarrhea The incubation period is usually 1 to 3 days followed by a sudden onset In the usual clinical course profuse watery stools occur which are voluminous and frequent and lack all fecal characteristics They are generally light gray (rice water) and contain small flecks of mucus but no pus Tenesmus does not occur Vomiting is copious and may be projectile without nausea or

retching With the tremendous loss of fluid dehydration and hypochloremia become severe and prostration is marked Generalized muscular cramps may cause severe pain Patients remain mentally clear but are extremely apathetic The circulation is markedly affected and peripheral collapse develops rapidly Renal failure with anuria and uremia occurs in severe cases The skin temperature may be subnormal while the rectal temperature is elevated In some cases high temperature results when complications develop such as pneumonia The disease runs its course in 3 to 5 days In properly treated cases the fatality rate is low but during epidemics among inadequately treated patients or those in debilitated states previous to the onset 50 to 70 per cent may die These estimates do not include the milder cases which escape notice

Laboratory Findings The rapid dehydration leads to hemoconcentration and the specific gravity of the blood may rise to 1 070 Large amounts of mineral metabolites are lost especially chloride sodium and calcium and acidosis results

Pathology The pathologic picture is unique in its simplicity as the effects of the infection resemble the results of an overdose of a drastic purgative or of severe food poisoning The gross changes in the intestine result from dehydration which causes pallor and some swelling of the Peyer s patches The cholera vibrios when killed liberate an endotoxin which acts as a severe intestinal irritant and causes denudation of the intestinal epithelium Diarrhea results from the increased permeability of the intestinal mucosa with outpouring of tremendous amounts of fluid Fatalities apparently result from dehydration with the loss of salts and the rapid development of azotemia The organisms live in the intestinal lumen and rarely penetrate the wall Whether the endotoxin has more general effects particularly on the kidney or whether the impairment of renal function is due solely to dehydration and ischemia is controversial

Differential Diagnosis Diagnosis of cholera in areas where the disease is known to be endemic is usually made on clinical findings It is essential to recognize the mild ambulatory cases which are *important potential carriers In an epidemic every* person with any type of gastrointestinal disturbance should be suspected of having cholera until it is proved otherwise The diseases often confused with cholera are acute bacillary dysentery in which the appearance of the stools is different tenesmus is present and collapse is rare in adults *Salmonella* food poisoning which is usually accompanied by nausea and retching with vomiting clinical forms of malaria in which intestinal symptoms with collapse occur heat exhaustion and other conditions leading to a state of shock

The specific diagnosis is based on bacteriologic identification of *V comma* from stool cultures or rectal swabs Smears of feces stained with diluted carbolfuchsin and showing comma forms with the fish in stream appearance are suggestive Cultures from stools in alkaline peptone water usually show the typical organisms concentrated at the surface in 6 hr Suspected colonies from streaks of nutrient agar may be tested with specific *V comma*-agglutinating serum by means of a slide technique

Treatment The natural course of the disease is short and the infection is self limited There is no evidence that the mortality rate is reduced by any of the sulfonamides or antibiotics The tetracycline drugs cause the stools to become negative in 2 or 3 days but do not alter the course of the disease Chloramphenicol has been used orally and intravenously with little effect The real emergency in treatment is to replace the enormous losses of water sodium and potassium The reduction of plasma volume leads to a lowering of blood pressure oliguria anuria and collapse The increased viscosity of the blood with increased erythrocyte mass prevents maintenance of proper circulation Patients who are not comatose or in shock usually recover with oral administration of 1 per cent sodium carbonate normal saline or 1/6 M sodium lactate solution in 50 to 100 ml amounts every half hour until 3 to 5 liters per day have been ingested

Patients who are comatose or in shock should be given intravenous infusions of normal saline or Ringer s lactate solution at the rate of 60 to 100 ml per min receiving 2 liters every 6 to 8 hr for the first 2 days The specific gravity of the blood or hemoglobin or hematocrit determinations may be used as a guide for the amount of fluid necessary Supplementary solutions containing potassium chloride are necessary during the first day of treatment 8 to 16 Gm should be administered over a 24 hr period Patients with severe abdominal cramps may require morphine Atropine by hypodermic or tincture of belladonna orally will decrease the number of stools Nourishment by mouth can be resumed gradually as the gastrointestinal symptoms subside

Prevention Cholera occurs where sanitary safeguards are ineffective Particular emphasis should be placed on proper water supply and food handling All cases and suspected carriers must be isolated Fly control by adequate screening of kitchens wards and latrines is important and destruction of flies and larvae by DDT sprays is effective

Cholera vaccine is employed and will give protection for 6 to 12 months but its value is definitely secondary to proper sanitation

Chloramphenicol and the tetracycline drugs are

more effective against the cholera organism in vitro than the sulfonamides and in patients will cause the organisms to disappear from fecal material in 2 days They may be used to prevent infections from known carriers and convalescent patients

Section 5 Other Gram-negative Bacillary Infections

125 HEMOPHILUS INFECTIONS

Louis Weinstein

The genus *Hemophilus* consists of nonmotile gram negative rods or coccobacilli which require specific growth factors (X and V) for multiplication The organisms of importance in human disease are *H influenzae H pertussis H ducreyi* the Koch Weeks bacillus and *Moraxella lacunata* Two other species are found in the pharynx of normal individuals and rarely may produce pharyngitis (*H hemolyticus*) or endocarditis (*H parainfluenzae*) The site invaded most frequently is the respiratory tract and the organisms responsible for the bulk of infections are *H influenzae* and *H pertussis*

HEMOPHILUS INFLUENZAE INFECTIONS

Hemophilus influenzae produces a wide variety of diseases in many organ systems The organism was first isolated by Pfeiffer during a pandemic of influenza in 1890 and was thought to be the causative agent of this disease During the 1918 influenza pandemic extensive bacteriologic investigations revealed a high incidence of *H influenzae* in the nasopharynx and lungs of patients in many parts of the world

Etiology *Hemophilus influenzae* is a gram negative nonsporulating pleomorphic rod In exudates the organisms are usually predominantly coccobacillary and can be mistaken for pneumococci or meningococci Some strains demonstrate bipolar staining and bacillary forms that vary from short rods to long filamentous ones occur The pleomorphism of the organism is its most striking feature

Hemophilus influenzae grows well on chocolate agar and Levinthal's medium which has the advantage of being transparent On Levinthal's agar typical colonies are iridescent when viewed by obliquely transmitted light when they are about 4 to 6 hr old this property disappears after 24 hr

Virulent strains of the influenza bacillus are encapsulated Although it had been thought that strains without capsules were nonpathogenic recent observations have implicated such strains in infections of the respiratory tract On the basis of specific capsular polysaccharides *H influenzae* may be classified into six types Type B produces about 95 per cent of human infections Three of the types are immunologically related to certain pneumococci Influenza bacilli lack certain enzyme systems common to most bacterial species and very little fermentation of carbohydrates takes place Like pneumococci this organism is soluble in bile

Epidemiology *Hemophilus influenzae* infects only man naturally It is not ordinarily invasive for any of the smaller animals although monkeys can be infected experimentally Although the pathogenicity of the influenza bacillus is closely related to the presence of the capsule nonencapsulated strains can also produce disease

The incidence of *H influenzae* infections is greatest in the winter and early spring Nose and throat cultures during these seasons reveal encapsulated or nonencapsulated strains in many asymptomatic individuals Penicillin therapy increases the incidence of positive throat cultures in a population

Children in the first 2 months of life have a high level of bactericidal antibody for *H influenzae* passively transferred from the mother Between the ages of two months and three years most children

show little serum bactericidal capacity but with aging the number of individuals whose blood exerts a lethal action against the organism increases

The influenza bacillus is transmitted by way of the respiratory tract from carriers or active cases of infection

Pathology The characteristic tissue response produced by *H influenzae* is acute suppurative inflammation Infections of the larynx trachea and bronchial tree are characterized by inflammation and edema of the mucosa and the presence of thick exudate and invasion of the lungs results in a bronchopneumonia similar to that produced by other bacteria Swelling of the small radicles of the bronchial tree is common and particularly in young children a severe diffuse bronchiolitis can occur In influenzal meningitis the vertex of the brain is covered with thick greenish yellow exudate

Microscopic examination of the lesions produced by *H influenzae* reveals an exudate consisting primarily of polymorphonuclear leukocytes and large numbers of organisms enmeshed in fibrin

Clinical Manifestations Infections due to *H influenzae* are usually accompanied by a constitutional reaction In severe disease there is high fever usually without rigors and generalized malaise In milder infections systemic manifestations are slight and fever is inconstant

The most important manifestations of influenzal infection result from disturbances at the primary sites of bacterial multiplication The commonest diseases produced by *H influenzae* are pharyngitis epiglottitis laryngotracheitis pneumonia bronchitis and bronchiolitis otitis media and meningitis The symptoms and signs of influenzal invasion of the respiratory tract or meninges are similar to those of infection of these areas by other organisms and differential etiologic diagnosis depends upon epidemiologic background the age of the patient and demonstration of the causative agent

Pharyngitis *Hemophilus influenzae* is a relatively common cause of pharyngitis in children and acute influenzal pharyngitis is being observed with increasing frequency in adults where it often occurs as a complication of the chemotherapy of other infections Examination of the throat usually reveals only marked redness and injection Very rarely patches of soft yellow exudate may be present The pharyngitis tends to persist for many days unless properly treated Discomfort in the pharynx is often out of proportion to the physical findings

Epiglottitis Disease of the upper respiratory tract produced by *H influenzae* is sometimes limited to the epiglottis which becomes reddened swollen and stiff Discomfort in the hypopharynx and "croupy breathing may progress to a point at which tracheotomy becomes necessary This disease is rare in adults

Laryngotracheobronchitis The entire laryngotracheobronchial tree may be the site of infection, with resulting rapidly progressive obstruction of the airway Croupy cough is accompanied by increasing signs of respiratory embarrassment and tracheotomy is sometimes necessary Influenzal laryngotracheitis is very rare in adults The disease can lead to death within 18 to 24 hr

Pneumonia Primary pneumonia due to *H influenzae* with rare exceptions is a disease of children. In the adult it is usually secondary to viral influenza measles or bacterial pneumonitis It may complicate rubeola or pertussis in the young Bacteremia occurs in approximately one third of the cases

Bronchitis and Bronchiolitis Severe diffuse bronchiolitis characterized by persistent nonproductive cough wheezing and dyspnea occurs in children Physical examination usually reveals lowering and fixation of the diaphragms prolonged expirations and typically asthmatic breathing Roentgenographic examination of the chest reveals increased radiolucence and flattening of the diaphragms consistent with emphysema This is an extremely serious illness and unless promptly recognized and treated may be rapidly fatal

Otitis Media *Hemophilus influenzae* is a common cause of suppurative otitis media in children the infection is uncommon in adults Influenzal middle ear disease is indistinguishable on clinical grounds from infection due to other bacteria

Meningitis The influenza bacillus is the commonest cause of meningitis between the ages of six months and two years and is frequent in later childhood In adults it may follow operation on or injury to the head The writer has studied one adult in whom spinal anesthesia in the presence of a severe sore throat was followed within 24 hr by meningitis due to type B *H influenzae* Ninety five per cent of cases are produced by type B organisms a few by type A and a rare one by nonencapsulated strains About two thirds of the patients have a preceding infection of the upper respiratory tract and about one third have bronchopneumonia Signs of meningeal irritation stiff neck and back and positive Kernig and Brudzinski signs are usually prominent except in very young babies in whom bulging of the fontanelles may be the only sign The diagnosis should be suspected because of the age of the patient and the frequent prodrome of respiratory infection it is confirmed by identification of the organisms from the spinal fluid or blood

Other Diseases Subacute and acute bacterial endocarditis may be produced by *H influenzae*

although more infections of the heart valves have been due to *H parainfluenzae* The influenza bacillus is a rare cause of suppurative *pericarditis* In the winter *acute conjunctivitis* may be due to *H influenzae* While there are no clinical features which distinguish this from "pink eye" produced by the Koch Weeks bacillus epidemics of conjunctivitis due to the latter are most common in the summer Although it has been suggested that *H influenzae* and the Koch Weeks bacillus are identical more recent observation has indicated that although they are antigenically related they are distinct species *Moraxella lacunata* is also an occasional cause of acute purulent conjunctivitis Acute pyogenic *arthritis* due to *H influenzae* has been reported One of the very important lesions in which this organism plays a role in the adult is *bronchiectasis* Together with other pyogenic bacteria it can be responsible for the perpetuation of this disease

Laboratory Findings As a rule infections due to *H influenzae* are accompanied by polymorphonuclear leukocytosis ranging from 15 000 to 30 000 per cubic millimeter In young children with severe disease leukopenia (2 000 to 3 000 leukocytes per cubic millimeter) with a deficiency of polymorphonuclear leukocytes can occur Bacteremia is of irregular occurrence in influenzal infections of the respiratory tract but is demonstrable in about 50 per cent of cases of meningitis

Course and Complications The course of *H influenzae* infections is influenced completely by the location of the disease Epiglottitis laryngotracheobronchitis bronchiolitis or pneumonia may be fulminating particularly in young children Some of these patients succumb to the uncontrolled infection but in many the cause of death is obstruction of the airway This cannot always be relieved by surgical methods because impediment to flow of air is most marked in the smaller radicles of the bronchial tree Virtually 100 per cent of untreated cases of influenzal meningitis terminate fatally Internal and external hydrocephalus brain abscess subdural empyema diffuse cortical necrosis and shock (the Waterhouse-Friderichsen syndrome) are possible complications With specific therapy the incidence of complications is generally sharply reduced However if subdural aspiration is carried out routinely in children with influenzal meningitis which is responding to antibiotics sterile fluid is demonstrable in about half the cases Neurologic disturbances from subdural effusions are uncommon Epileptiform seizures can occur while the disease is responding favorably to chemotherapy

Treatment Specific serotherapy is presently used only in unusual situations The sulfonamides streptomycin the tetracyclines and chloramphenicol inhibit *H influenzae* Streptomycin is very effective but has the disadvantage of leading to the rapid development of bacterial resistance Sulfadiazine or sulfisoxazole (Gantrisin) is effective in influenzal pharyngitis but the tetracycline compounds are more active than the sulfonamides and are preferred for the therapy of lesions involving the respiratory tract There is controversy concerning the treatment of influenzal bacterial meningitis but several facts are clear The sulfonamides should never be used alone Streptomycin given both intramuscularly and intraspinally reduces the mortality rate but about 10 per cent of patients develop drug resistant organisms 48 to 72 hr after initiation of treatment The tetracyclines alone do not eradicate the meningeal infection Chloramphenicol (50 to 75 mg per kg body weight per day) and sulfadiazine (0 1 Gm per lb body weight per day the initial dose being one half the quantity required daily) constitute the preferred regimen in many clinics Death or complications still occur and clearing of the organisms from the spinal fluid may be delayed In the writer's experience the most effective therapy is as follows Streptomycin (no more than 25 mg in children under age three and 50 mg in older ones) diluted in 10 ml saline is injected intraspinally at the time the diagnosis is established and once again 12 hr later the drug is not administered intraspinally after the second dose Streptomycin (0 5 to 1 0 Gm daily in divided doses depending on the age and size of the patient) is given intramuscularly and sulfadiazine or sulfisoxazole (Gantrisin) is administered in quantities sufficient to produce a blood level of 12 to 15 mg per 100 ml Treatment is continued for 2 weeks In 40 consecutive cases of influenzal meningitis so treated there have been no deaths and no detectable complications

PERTUSSIS

Whooping cough is a common disease which affects about 65 per cent of all unimmunized children It is characterized by an inflammatory reaction involving the entire respiratory tract which produces paroxysmal cough and the typical inspiratory stridor or "whoop"

Etiology The causative agent is *Hemophilus pertussis* a short or ovoid gram negative nonmotile nonsporulating facultatively anaerobic bacillus It shows very little tendency towards pleomorphism Bipolar staining is frequent and encapsulation can be demonstrated by special stains

The pertussis bacillus requires both the X and V factors for growth especially for initial isolation and multiplies best on Bordet Gengou medium

Hemophilus pertussis is a uniform antigenic species without fixed variation or types

The pertussis bacillus produces no demonstrable endotoxin although it has been postulated that some of the clinical features of whooping cough may be due to such material definite evidence for this is lacking

Epidemiology Pertussis is world wide and may be endemic or epidemic If the disease has not been present for several years it tends to assume epidemic proportions when it reappears In some geographic locations the disease is most common during the winter and in others it is seen with greatest frequency in the late summer and fall The index of contagion is 80 to 100 per cent about 200 000 cases occur in the United States each year

Approximately 40 per cent of cases of pertussis occur in the first two years of life the same number is observed between two and five years At least 50 per cent of all children have had whooping cough before they reach the age of five and 75 per cent by the age of seventeen

Pertussis is spread by droplets from the respiratory tract It has been suggested that rarely the organisms may be transmitted by fomites The infectivity of the disease during the incubation period is questionable it is most contagious during the catarrhal stage Healthy carriers play no role in dissemination mild or missed cases are of great importance The duration of contagiousness is about 4 to 6 weeks

Pathology The initial lesion in whooping cough is hyperplasia of the peribronchial lymphoid tissue and tracheobronchial lymph nodes Subsequently or perhaps coincidentally the bronchi trachea larynx and nasopharynx are involved in a necrotizing inflammatory reaction The organisms are present in large numbers between the cilia of the epithelial cells lining the trachea and bronchi It has been thought that the pulmonary alveoli are not involved in pertussis but there is often a diffuse bronchopneumonia with marked desquamation of the alveolar epithelium and lymphocytic infiltration of the peribronchial tissues and alveolar walls

Clinical Manifestations The incubation period of whooping cough averages 12 to 15 days although it can be as long as 20 days The first clinical manifestations are nonspecific consisting of slight nasal discharge conjunctivitis and mild cough without fever This *catarrhal stage* lasts for 7 to 14 days

The *paroxysmal phase* of pertussis follows the *catarrhal stage* and is characterized by paroxysms of coughing ending in a loud crowing inspiratory noise (the whoop) the expulsion of varying quantities of thick mucoid sputum from the respiratory tract and vomiting Episodes of cough may be as few as 1 or 2 or as many as 40 to 50 per day Children under the age of six months frequently do not whoop The mere presence of a whoop is in itself not diagnostic of pertussis Rarely the paroxysms of coughing and whooping are replaced completely by sneezing

Fever of appreciable degree does not occur in the paroxysmal phase of pertussis unless complications are present Vomiting frequently follows spells of coughing but is not a specific manifestation of the disease Soreness over the trachea and main bronchi are common Spasm ulcer and more rarely edema of the glottis sometimes occur In cases with severe vomiting and inability to retain food serious inanition wasting and tetany may appear

There is a bleeding tendency in pertussis This has been attributed to the effect of an angiotoxin (not proved) elaborated by the organism which increases the ease of rupture of blood vessel walls. Hemoptysis epistaxis purpura and subconjunctival or intestinal hemorrhages may occur but are usually of little clinical significance

Physical examination in pertussis is often entirely normal There may be redness and injection of the blood vessels of the nose and pharynx Although there are usually no abnormal findings in the lungs fine crackling "sticky" rales are sometimes present. There are ulcers of the frenum of the tongue in about 20 per cent of cases these occur only when the lower central incisor teeth are present

The paroxysmal stage of pertussis usually lasts from 1 to 6 weeks When coughing persists beyond 6 weeks it is usually due to the development of a so called habit whoop and not to continuation of the disease

Laboratory Findings The peripheral white blood count is as a rule elevated in pertussis The total count may be over 100 000 per cubic millimeter and lymphocytes may constitute 90 per cent of the cells All the lymphocytes are mature This helps to distinguish the blood picture from that of acute leukemia but not from acute lymphocytosis Blood cultures are sterile Cultures of the upper part of the nasopharynx reveal *H pertussis* the incidence of positive isolations varying with the stage of the disease X ray study of the lungs in the uncomplicated case usually reveals only hilar lymphadenopathy and increase in the density of the bronchovascular markings

Complications Bronchopneumonia occurs in from 1 to 10 per cent of cases the organisms most frequently involved are the beta hemolytic *Streptococcus Diplococcus pneumoniae Staphylococcus aureus H influenzae* and *H pertussis* When pneumonitis appears during the course of chemotherapy the bacteria most often responsible are *Escherichia coli Proteus* strains *Aerobacter aerogenes* or *Pseudomonas aeruginosa* Another impor

tant complication is atelectasis small areas of collapse are an almost constant finding in this infection but major portions or even a whole lung may be involved Pneumothorax is rare

The severe coughing of pertussis may lead to several complications Hemorrhage may appear in the anterior chamber of the eye or in the retina Detachment of the retina and blindness develop in rare cases Prolapse of the rectum and inguinal or umbilical hernias have been noted Otitis media is observed in about 10 per cent of cases the organisms most frequently involved are the beta hemolytic *Streptococcus* and *S aureus* although *H pertussis* is sometimes responsible

Nervous system manifestations are not rare in pertussis The commonest is convulsions they often come with the sudden fever of secondary bacterial infection Other causes of seizures are encephalopathy (1 to 14 per cent of cases) multiple petechial or gross hemorrhages of the brain and cerebral hypoxia due to the combined effect of anoxic anoxia and venous stasis in the brain The encephalopathy is characterized by an increase in the protein and cell content of the spinal fluid Its etiology is unknown Hyperreflexia nuchal rigidity cranial nerve palsies areflexia extensor plantar responses flaccid hemiplegia spasticity of the extremities opisthotonos difficulty in speaking twitching papilledema nystagmus blindness strabismus and difficulty in swallowing can all occur Some of the more important residua are mental retardation recurrent convulsions behavior and personality disorders amnesia aphasia diffuse cerebral atrophy chorea athetosis hydrocephalus epilepsy and idiocy

Diagnosis The diagnosis of pertussis can frequently be made on clinical grounds alone A known contact is helpful but the appearance of paroxysms of typical coughing and whooping after a short period of an undefined upper respiratory tract infection is strongly suggestive It must be stressed however that in babies under the age of six months there is usually only paroxysmal coughing without the characteristic whoop

An increased white blood count with a large increase in lymphocytes is characteristic the lymphocyte count must however be evaluated in relation to the age of the patient

Isolation of *H pertussis* from the respiratory tract establishes the diagnosis unfortunately this is not possible in many cases Using cough plates and nasopharyngeal swabs positive cultures can be obtained in 90 per cent of patients in the catarrhal stage of the disease pertussis however is rarely seen by the physician in this phase The incidence of positive cultures is lower after paroxysmal coughing appears and decreases with the duration of symptoms

Serologic studies are of little or no help in establishing the presence of pertussis

Prevention Active immunization is effective in preventing pertussis in the majority of individuals who are given vaccine Immunization may be started at the age of three months both antibody production and protection against invasion by *H pertussis* result If the procedure is carried out at this early age a "booster" injection should be administered at the end of the first year of life and again just before the child starts to school Although it is not commonly practiced passive immunity can be conferred on the newborn child by active immunization of the mother beginning in the sixth or seventh month of pregnancy Vaccine should not be given in the presence of the active disease not only is it useless but it may provoke serious neurologic reactions

In children who have been exposed to a case of pertussis but have not been actively immunized passive protection may be given by the injection of 20 to 30 ml human hyperimmune pertussis antiserum or 2 ml immune gamma globulin as soon as possible after exposure and again 1 week later Such prophylaxis is 75 to 85 per cent effective

Treatment Although most of the antimicrobial drugs have been employed in the treatment of pertussis there is no incontrovertible evidence that they are strikingly beneficial Aureomycin (chlortetracycline) chloramphenicol Terramycin (oxytetracycline) and erythromycin have been used but the results obtained in controlled studies are not remarkable

There are few controlled studies of serum therapy in whooping cough but in many clinics it is the practice to administer human hyperimmune serum (20 ml every 48 hr for 3 doses) or immune gamma globulin (2 ml every 48 hr for 3 doses) to all children with pertussis under the age of two years

Most important in the program of therapy is repair of the water and salt loss which follows severe and frequent vomiting If failure to retain food is combatted by prompt refeeding whooping cough patients can be made to maintain or gain weight

Early detection and treatment of complications is one of the most important factors in the reduction of mortality in pertussis The prompt recognition of secondary bacterial infections of the lungs or middle ear and therapy with a properly selected antibiotic agent lead to cure in practically all cases When gross atelectasis occurs correction by tracheal catheter suction or bronchoscopy may be lifesaving Little can be done to influence the course or outcome of such complications as gross cerebral hemorrhage or encephalopathy

Proper management of whooping cough has made

the outlook for complete recovery excellent There have been only two fatalities in 500 patients with this infection in the last 8 years in the writer's clinic neither was due to a preventable or treatable complication

126 CHANCROID

Albert Heyman

Definition Chancroid is an acute localized venereal disease caused by the Ducrey bacillus It is characterized by ulceration at the site of inoculation and by enlargement and suppuration of the regional lymph nodes

Etiology The etiologic agent of chancroid the Ducrey bacillus is a short plump gram negative organism with rounded ends When stained by special methods the bacillus exhibits bipolar staining In the stained smears of genital lesions the organisms usually appear singly or in small clusters but they may be arranged in long parallel columns between cells or shreds of mucus Occasionally the bacilli are situated intracellularly The organism can be cultivated in whole defibrinated blood or nutrient broth containing blood When grown in pure culture in a liquid medium the Ducrey bacillus appears in long tangled chains composed of both coccal and bacillary forms

Incidence The number of cases of chancroid occurring every year cannot be determined satisfactorily since accurate diagnosis of this condition is not generally attempted A diagnosis of chancroid is frequently applied to genital lesions improving with sulfonamide therapy in which the *Treponema pallidum* cannot be demonstrated The disease is encountered in the West Indies North Africa and the Orient particularly in the lower economic groups of the population It is also prevalent in the Southeastern part of the United States and is more frequent in Negroes than in whites Approximately 2 900 cases were reported in the United States in 1955 the true incidence is probably considerably higher

Pathogenesis Chancroid is usually contracted by sexual intercourse and the lesions are almost always located about the genitalia The disease can apparently be acquired from sexual partners who show no evidence of an active chancroidal infection The organism has been cultivated from the smegma and vaginal secretions in patients without clinical manifestations of the disease Such individuals may be carriers of the Ducrey bacillus The organism readily produces an infection when inoculated into open or slightly abraded areas of the skin or mucous membranes Chancroidal ulcerations frequently occur in areas of the genitalia where minor abrasions may be present (fourchette of the vulva edge of phimotic prepuce and frenum) After an incubation period of 2 to 5 days a localized ulceration appears at the site of inoculation This may be followed later by inflammation and suppuration of the regional lymph nodes

Chancroidal infection produces a distinct histologic appearance The base of the ulcer is a shallow zone made up of polymorphonuclear leukocytes fibrin red blood cells and necrotic tissue Below this is a fairly wide layer consisting chiefly of proliferating endothelial cells and newly formed blood vessels some of which show degeneration of their

walls Finally there is a deep zone in which a dense infiltration of plasma cells and lymphocytes occurs This histologic pattern is sufficiently characteristic to permit differentiation from other genital lesions Biopsy is a valuable diagnostic procedure

Clinical Manifestations The typical chancroidal lesion is a painful shallow irregular ulcer with ragged undermined edges a granular friable base and a dirty yellow exudate The lesion is characteristically nonindurated and for this reason has been called *soft chancre* The size of the ulceration varies but seldom exceeds 2 cm in diameter Multiple lesions resemble a folliculitis or pyogenic infection Almost any portion of the genitalia may be involved but extragenital lesions are rare In about 50 per cent of the patients inflammation and suppuration of the inguinal lymph nodes will occur The term *bubo* is given to this type of lymphadenitis The chancroidal bubo develops rapidly and becomes a very painful inflammatory inguinal mass When suppuration occurs the mass may become tensely fluctuant and may rupture spontaneously leaving a large single craterlike abscess Mild constitutional symptoms may accompany the involvement of the inguinal lymph nodes and the patient may complain of headache malaise fever or anorexia

Diagnosis Although the clinical appearance of chancroid is often sufficiently characteristic to suggest the correct diagnosis laboratory confirmation is desirable Stained smears or culture of the exudate taken from the undermined edge of the lesion will reveal the Ducrey bacillus in the majority of the early cases The organism is not easily demonstrated however in larger lesions when secondary bacterial contamination has occurred Biopsy is feasible in such cases and is an efficient method of diagnosis Attempts to demonstrate the organism in the buboes by either culture or smear usually are not successful The majority of patients with chancroidal infection will exhibit a positive skin reaction to an intradermal injection of killed Ducrey bacilli The value of this skin test is limited by the fact that a positive reaction persists for years after exposure to the infection One cannot be certain therefore whether a positive skin test in an individual patient represents the existing chancroidal infection or a previous one Early syphilis may be present concurrently with chancroid in these patients Serologic tests and dark field examination of the lesions and regional lymph nodes should be done to rule out this possibility

Treatment Sulfadiazine or Gantrisin is the drug of choice in the treatment of chancroid doses of 4 Gm a day for 7 to 12 days are usually curative Local medication is not necessary but saline soaks and cleanliness are advised Although the buboes usually subside with sulfonamide therapy fluctuation may persist and the node should be aspirated in order to prevent spontaneous rupture Streptomycin chloramphenicol, and the tetracyclines in doses of 2 Gm a day for 7 to 10 days will each produce satisfactory healing of the lesions of chancroid The use of these agents is rarely necessary since sulfadiazine is equally effective The antibiotics with treponemicidal properties should not be used in the treatment of chancroid until repeated dark field examination and serologic tests have ruled out the possibility of early syphilis

127 BRUCELLOSIS (Undulant Fever)

Wesley W Spink

Definition Brucellosis is an infectious disease due to microorganisms belonging to the genus *Brucella* and is transmitted to man from lower animals The acute form of the illness is frequently characterized by a febrile illness without localizing findings while the chronic form is featured by fever weakness and vague complaints which may persist for months and years

History Accurate clinical descriptions of brucellosis have been ascribed to Hippocrates but the first clear cut picture of the disease was presented in 1863 by Marston who as a British Army surgeon in Malta detailed his own case and those of others The etiologic agent was discovered by Bruce in 1886 The outstanding clinical description of the disease is contained in the monograph by Hughes published in 1897 Wright and Semple in 1897 demonstrated agglutinins for *Brucella* in human blood In the same year Bang reported that *Bacillus abortus* was the cause of contagious abortion in cattle in Denmark The Mediterranean Fever Commission Reports of 1905 to 1907 detail the classic studies on epidemiology The first recognized human case of brucellosis in the United States occurred in a nurse in Washington D C and was described by Craig in 1906 In 1911 brucellosis was found to be endemic in the goats of Texas and Gentry and Ferenbaugh traced human cases to this source Traum first identified *Brucella* from aborting sows in 1914 and Evans in 1918 distinguished the difference between *Brucella melitensis* and *Brucella abortus* and suggested that raw milk

from infected cows could be the source of human cases In 1924 Keefer described the first human case of brucellosis in this country due to organisms other than *Br melitensis*

Etiology Human brucellosis is due to one of three species of *Brucella*—viz *Br melitensis* (goats) *Br suis* (hogs) and *Br abortus* (cattle) *Brucella* are small nonmotile non spore forming rods staining gram negative Growth is best supported at 37 C in trypticase soy broth or tryptose phosphate broth having a pH of 6 6 to 6 8 The primary isolation of *Br abortus* requires displacement of 10 per cent of the air by carbon dioxide The differentiation of the three species is dependent upon biochemical and serologic reaction In general *Br melitensis* is the most invasive of the three species which fact is reflected in the severity of human infections while *Br abortus* is the least virulent

Epidemiology The natural reservoir of brucellosis is in domestic animals particularly cattle swine goats and sheep The disease is very rarely transmitted from human to human By and large man acquires brucellosis through the ingestion of milk or milk products containing viable *Brucella* or through contact of the skin with infected tissues excretions and secretions Recent epidemiologic studies in the United States indicate that the majority of cases are acquired through contact and fewer and fewer cases are caused by the ingestion of milk This trend is due to the enactment of local and state ordinances requiring all milk sold for human consumption to be pasteurized There is some evidence that brucellosis may be air borne with the disease resulting from the inhalation of *Brucella* Infections caused by *Br abortus* are spread through cow s milk or through dermal contact with *Brucella* Epidemics of brucellosis traced to raw cow s milk have been caused by *Br abortus* Contact with infected porcine tissue is a common cause of infections due to *Br suis* While infections due to *Br melitensis* result from eating goat s cheese or drinking unpasteurized goat s milk studies in Minnesota and Iowa have shown that contact with infected hogs has been the source of *melitensis* infections It is readily appreciated why brucellosis is primarily a disease of rural areas and why it is considered an occupational disease involving meat packing plant employees farmers veterinarians and livestock producers

Pathogenesis Following invasion of the body by *Brucella* through the oropharynx or through the skin the organisms tend to localize in tissues of the reticuloendothelial system such as the bone marrow lymph nodes liver spleen and also the kidneys A characteristic but nonspecific reaction of these tissues to the *Brucella* is the appearance of epithelioid cells giant cells of the foreign body and Langhans types and lymphocytes and plasma cells Necrosis and caseation rarely occur in these granulomatous areas When caseation is encountered it is usually caused by *Br suis* The granulomas are similar to those of sarcoidosis and tuberculosis Other less frequent sites of localization of *Brucella* are the bones especially the spine the endocardium and the testes While the central nervous system and peripheral nerves are commonly affected deleteriously by *Brucella* the mechanism whereby this takes place is not known Like other blood borne infections *Brucella* may on occasion localize in any tissue or organ in the body Though brucellosis is a common cause of abortions in cattle swine and goats authentic cases of human abortions occur no more frequently in this disease than in other bacteremias Orchitis in the male is rarely the cause of subsequent sterility

Manifestations The incubation period varies between 5 and 21 days though many months may elapse between the time of infection and the first appearance of symptoms The onset in many instances may be insidious the patients exhibiting a low grade fever with no localizing findings and complaining of headache weakness insomnia, sweats anorexia constipation pain over the spine and generalized aches and pains Less frequently the disease may be ushered in by chills high fever and prostration but again, localizing abnormal physical findings may be absent In general, about 50 per cent of the patients exhibit enlarged lymph nodes especially of the cervical region and splenomegaly is detected in about one third of the cases An enlarged and tender spleen is usually associated with the more severe cases Pain on pressure over the vertebrae occurs occasionally Pain distributed over the course of the peripheral nerves particularly the sciatic nerve is encountered Orchitis appears after several days of illness and like the orchitis of mumps is ushered in with a chill or chilliness high fever and tender and enlarged testes Painful and swollen joints are seen occasionally but persistent and deforming arthritis is not specific for the disease Signs and symptoms referable to the lungs and pleurae are uncommon A rare but serious complication is subacute bacterial endocarditis Ocular disorders are associated with the more chronic forms of the disease

The initial febrile stage of the illness may endure for only a few days or up to several weeks The persistence of fever and symptoms is definitely related to physical activity Rest in bed during the acute illness is frequently associated with prompt improvement The natural course of the disease in the majority of patients is marked by a permanent remission of fever and symptoms within 3 to 6

months A small number of bacteriologically proved cases may have an illness that persists longer than 1 year

The present status of chronic brucellosis is extremely difficult to assess There is no doubt that the infection may persist in some individuals for months and years Such patients exhibit a state of ill health manifested by weakness fatigue mental depression vague aches and pains and no abnormal physical findings Intermittent fever may occur The precise incidence of chronic brucellosis awaits further investigation Much of the data now available is based upon uncritical clinical and laboratory studies

Laboratory Procedures A precise diagnosis of brucellosis is dependent upon the results of laboratory procedures

Blood The total leukocyte count is usually normal or slightly reduced but is rarely over 10 000 cells per cubic millimeter The differential count reveals a relative lymphocytosis The erythrocyte sedimentation rate is of no specific diagnostic aid the rates being normal or accelerated

The most practical method for screening suspected cases of brucellosis is the *agglutination* reaction Agglutinins usually appear during the second or third week of illness If proper techniques and antigen are employed agglutinins are demonstrated in the vast majority of bacteriologically proved cases Active brucellosis is usually associated with titers of 1 100 or above Agglutinins for brucellosis are not always specific since cross reactions occur with the cholera vibrio and with *Pasteurella tularensis* Agglutinins may persist in the blood long after the patient has recovered

At least *one culture* of blood and preferably more should be carried out in every suspected case of brucellosis Cultures of *Brucella* have been isolated from aspirated sternal bone marrow when simultaneous blood cultures remained sterile It is too impractical for routine purposes to attempt to isolate *Brucella* from the urine bile or feces

The *opsonocytophagic test* which is a measure of the phagocytosis of *Brucella* by polymorphonuclear neutrophil leukocytes is of extremely doubtful diagnostic aid The *complement fixation test* does not contribute enough additional information to warrant its use

Intradermal Tests Various antigenic preparations including killed organisms are used widely for diagnostic purposes A positive reaction has no more significance than that obtained with tuberculin in suspected cases of tuberculosis A positive reaction indicates previous invasion of the body by *Brucella* and does not mean that active disease is present Unfortunately many instances of chronic brucellosis are being diagnosed on the basis of a vague illness and positive intradermal tests When agglutinins are absent and cultures remain sterile considerable caution must be exercised before making a diagnosis of brucellosis even though the skin test is positive Negative skin tests are encountered in severe cases of brucellosis where a high titer of agglutinins is present and a bacteremia is demonstrated

In summary the diagnosis of brucellosis depends upon a correlation of epidemiologic data the nature of the illness and laboratory information, such as the presence of agglutinins and isolation of *Brucella* from the tissues or blood

Differential Diagnosis Brucellosis must be differentiated from other acute febrile illnesses such as *influenza* and other *upper respiratory diseases* of doubtful etiology Brucellosis is not commonly associated with coryza or pharyngitis Other diseases from which it must be differentiated include *malaria* and *typhoid fever* Brucellosis may be confused with *infectious mononucleosis* but the characteristic blood picture and the elevated titer of heterophil antibodies in the latter disease are helpful differential aids

Chronic brucellosis simulates *psychoneurosis anxiety states* and *chronic nervous exhaustion* Indeed a patient with brucellosis may suffer from the foregoing nervous disorders Some confusion may arise in differentiating it from other diseases including tuberculosis and lymphoblastoma especially Hodgkin s disease

Treatment Unfortunately much information of a popular nature on brucellosis has been disseminated widely The general public has heard or read that brucellosis is a chronic disease which may last for years and that no satisfactory treatment is available Therefore any physician who believes that he is dealing with a case of brucellosis should reassure the patient that the disease is self limiting and that complete recovery will ensue Psychotherapy is extremely important in the management of these mentally depressed and tired patients The acutely ill and febrile patient should be kept in bed Many patients will recover completely following a period of rest

Over the years the lack of specific treatment for brucellosis has been emphasized by the number of agents and procedures that have been recommended and then discarded one by one Although sulfanilamide and its various derivatives can suppress the growth of brucellae these agents are unsatisfactory for the treatment of human brucellosis Penicillin is an ineffective drug for brucellosis Streptomycin and dihydrostreptomycin are unusual drugs in that they not only inhibit growth of brucellae but they can kill large numbers of the organisms within a relatively short period of time However strepto-

from infected cows could be the source of human cases In 1924 Keefer described the first human case of brucellosis in this country due to organisms other than *Br melitensis*

Etiology Human brucellosis is due to one of three species of *Brucella*—viz *Br melitensis* (goats) *Br suis* (hogs) and *Br abortus* (cattle) *Brucella* are small nonmotile non spore forming rods staining gram negative Growth is best supported at 37 C in trypticase soy broth or tryptose phosphate broth having a pH of 6 6 to 6 8 The primary isolation of *Br abortus* requires displacement of 10 per cent of the air by carbon dioxide The differentiation of the three species is dependent upon biochemical and serologic reaction In general *Br melitensis* is the most invasive of the three species which fact is reflected in the severity of human infections while *Br abortus* is the least virulent

Epidemiology The natural reservoir of brucellosis is in domestic animals particularly cattle swine goats and sheep The disease is very rarely transmitted from human to human By and large man acquires brucellosis through the ingestion of milk or milk products containing viable *Brucella* or through contact of the skin with infected tissues excretions and secretions Recent epidemiologic studies in the United States indicate that the majority of cases are acquired through contact and fewer and fewer cases are caused by the ingestion of milk This trend is due to the enactment of local and state ordinances requiring all milk sold for human consumption to be pasteurized There is some evidence that brucellosis may be air borne with the disease resulting from the inhalation of *Brucella* Infections caused by *Br abortus* are spread through cow s milk or through dermal contact with *Brucella* Epidemics of brucellosis traced to raw cow s milk have been caused by *Br abortus* Contact with infected porcine tissue is a common cause of infections due to *Br suis* While infections due to *Br melitensis* result from eating goat s cheese or drinking unpasteurized goat s milk studies in Minnesota and Iowa have shown that contact with infected hogs has been the source of *melitensis* infections It is readily appreciated why brucellosis is primarily a disease of rural areas and why it is considered an occupational disease involving meat packing plant employees farmers veterinarians and livestock producers

Pathogenesis Following invasion of the body by *Brucella* through the oropharynx or through the skin the organisms tend to localize in tissues of the reticuloendothelial system such as the bone marrow lymph nodes liver spleen and also the kidneys A characteristic but nonspecific reaction of these tissues to the *Brucella* is the appearance of epithelioid cells giant cells of the foreign body and Langhans types and lymphocytes and plasma cells Necrosis and caseation rarely occur in these *granulomatous* areas When caseation is encountered it is usually caused by *Br suis* The granulomas are similar to those of sarcoidosis and tuberculosis Other less frequent sites of localization of *Brucella* are the bones especially the spine the endocardium and the testes While the central nervous system and peripheral nerves are commonly affected deleteriously by *Brucella* the mechanism whereby this takes place is not known Like other blood borne infections *Brucella* may on occasion localize in any tissue or organ in the body Though brucellosis is a common cause of abortions in cattle swine and goats authentic cases of human abortions occur no more frequently in this disease than in other bacteremias Orchitis in the male is rarely the cause of subsequent sterility

Manifestations The incubation period varies between 5 and 21 days though many months may elapse between the time of infection and the first appearance of symptoms The onset in many instances may be insidious the patients exhibiting a low grade fever with no localizing findings and complaining of headache weakness insomnia sweats anorexia constipation pain over the spine and generalized aches and pains Less frequently the disease may be ushered in by chills high fever and prostration but again localizing abnormal physical findings may be absent In general about 50 per cent of the patients exhibit enlarged lymph nodes especially of the cervical region and splenomegaly is detected in about one third of the cases An enlarged and tender spleen is usually associated with the more severe cases Pain on pressure over the vertebrae occurs occasionally Pain distributed over the course of the peripheral nerves particularly the sciatic nerve is encountered Orchitis appears after several days of illness and like the orchitis of mumps is ushered in with a chill or chilliness high fever and tender and enlarged testes Painful and swollen joints are seen occasionally but persistent and deforming arthritis is not specific for the disease Signs and symptoms referable to the lungs and pleurae are uncommon A rare but serious complication is subacute bacterial endocarditis Ocular disorders are associated with the more chronic forms of the disease

The initial febrile stage of the illness may endure for only a few days or up to several weeks The persistence of fever and symptoms is definitely related to physical activity Rest in bed during the acute illness is frequently associated with prompt improvement The natural course of the disease in the majority of patients is marked by a permanent remission of fever and symptoms within 3 to 6

Prevention As long as the reservoir of brucellosis persists in domestic animals human brucellosis will occur The only practical means of eliminating the disease in human beings is to eradicate the disease from cattle hogs sheep and goats Control measures in animals are being worked out in several areas in the United States Since human brucellosis is contracted through the ingestion of contaminated milk and milk products it is essential that only properly pasteurized milk be utilized for human consumption Brucellosis is an occupational disease involving farmers livestock workers veterinarians and those working in packing plants There are no dependable and safe means available for immunizing these groups against the disease

128 TULAREMIA

Leighton E Cluff and Ivan L Bennett Jr

Definition Tularemia (rabbit fever deer fly fever Ohara s disease) is an infectious disease of animals transmitted to man by direct contact or by insect vectors A cutaneous or mucous membrane lesion at the site of inoculation and regional lymph node enlargement are the characteristic manifestations of the disease in the human being

History The microorganism responsible for tularemia was identified by McCoy and Chapin in 1912 among infected ground squirrels in Tulare County Calif The first description of tularemia in man was that by Wherry and Lamb in 1914

Etiology *Pasteurella tularensis* is a pleomorphic nonsporulating gram negative bacillus It can be cultured only on media containing glucose cystine and serum Thorough cooking renders meat from infected animals safe for consumption but tularemia can develop in persons handling carcasses that have been frozen for many days *Pasteurella tularensis* is related antigenically to the causative organisms of brucellosis and plague and possesses an endotoxin similar to those of many other gram negative bacteria

Epidemiology and Pathogenesis Contact with infected animals is the commonest source of tularemia in man but the disease also may be acquired from insects or by exposure to the organism in the laboratory A variety of rodents carnivores ungulates birds and arthropods are naturally infected by *Past tularensis* including rabbits squirrels woodchucks muskrats skunks coyotes foxes opossums mice rats quail chickens pheasants snakes ticks and flies The Rocky Mountain tick Western wood tick Eastern dog tick and the Lone Star tick (*Dermacentor andersoni D variabilis D occidentalis* and *Amblyomma americanum*) may act as reservoirs of infection One species of deer fly (*Chrysops discalis*) and a mosquito (*Aedes cinereus* in Sweden) can transmit tularemia to man Ticks are an important reservoir of the disease because the microorganism is transferred transovarially from the female to her progeny Sporadic and epidemic tularemia have occurred following contact with water and fish contaminated by infected animal carcasses However human to human transmission of infection probably does not occur Wild cottontail rabbits are the principal source of tularemia in the United States

Man is highly susceptible to tularemia the organism usually invades through the skin mucous membrane or gastrointestinal tract Hunters butchers and housewives are most often affected through exposure to infected animals

Pathology Microscopically the primary cutaneous lesion shows neutrophilic infiltration granulomatous reaction and necrosis The regional lymph nodes develop similar changes and often suppurate The granulomatous reaction in tularemia consists of giant and epithelioid cells and lesions resembling tubercles may occur in liver spleen lung and kidney *Pasteurella tularensis* has been recovered from lymph nodes many days after apparent subsidence of the disease

Manifestations The incubation *period is 3 to 7* days A typical lesion of skin or mucous membranes is not invariably present and therefore tularemia has classically been separated into several clinical types

More than 80 per cent of *infections by Past tularensis* are associated with a *lesion of* the skin or mucous *membranes* which has no distinguishing characteristics It begins as a reddened papule that may be pruritic and soon ulcerates The *primary* lesion in this *ulceroglandular* form of the disease is rarely very painful is usually *present before* onset of systemic symptoms *and may not heal* until

mycin is a poor therapeutic agent in brucellosis because while the antibiotic is quite lethal for extracellular brucellae intracellular brucellae are protected against the drug But there is no question that simultaneous treatment with streptomycin or dihydrostreptomycin and sulfadiazine is much more effective in human brucellosis than the administration of either the antibiotic or sulfonamide alone Streptomycin or dihydrostreptomycin can be given intramuscularly in a dose of 0 5 Gm every 12 hr for 2 weeks At the same time 1 Gm sulfadiazine is administered orally four times daily and continued for 3 weeks

Although the combination of streptomycin and sulfadiazine proved to be a definite advance in the therapy of brucellosis superior results have been obtained with the use of chlortetracycline (Aureomycin) *administered orally in a dose of 0 5 Gm* four times daily for a minimum of 3 weeks Relapses can often be treated successfully with a second course of chlortetracycline Similar results can be obtained with oxytetracycline (Terramycin) using the same doses Chloramphenicol (Chloromycetin) does not appear to be so satisfactory an antibiotic for brucellosis as the tetracyclines and its use is not recommended

There is evidence that *a combination of streptomycin or dihydrostreptomycin with one of the tetracycline drugs* provides a more efficient form of therapy than the tetracyclines alone The policy at the University of Minnesota clinics is to use one of the tetracycline antibiotics alone for the average case of brucellosis due to *Br abortus* in doses as recommended above However for more severe cases and for all those due to *Br melitensis* or *Br suis* streptomycin or dihydrostreptomycin is given intramuscularly in a dose of 0 5 Gm every 12 hr for 2 weeks along with an oral dose of 0 5 Gm tetracycline administered four times daily Treatment with the latter drug is usually kept up for 3 weeks

Patients with acute brucellosis often exhibit a severe toxic state which simulates typhoid fever and which gradually subsides after several days of therapy with antibiotics *However rapid and dramatic improvement* occurring within 8 to 12 hr can be obtained with the use of one of the adrenocorticoid steroid preparations An initial dose of *100 mg hydrocortisone can be given intravenously* followed by an oral dose of 25 mg four times daily Cortisone can also be employed orally in a dose of 50 mg four times daily Any steroid therapy should be discontinued after 72 to 96 hr and appropriate antibiotics should always be administered simultaneously

A common therapeutic practice in the more chronic cases is to attempt desensitization of the tissues to *Brucella* by treating patients with one of the several antigenic preparations such as heat killed *Brucella* cells or filtrates of *Brucella* cultures While hypersensitivity to *Brucella* is a factor in the symptomatology and the use of ascending doses of antigenic material may be sound therapy the results are difficult to evaluate and treatment must often be continued for several months Violent local and systemic reactions often occur even following the *injection of minute amounts of antigen*

For the relief of headache and the generalized aches and pains salicylates may be prescribed the occasional use of barbiturates is desirable for the insomnia which is so commonly a part of the disease

Prognosis While brucellosis may be a chronic and disabling disease the over all mortality rate is not more than 2 to 3 per cent and is negligible *when appropriate antibiotic therapy is promptly* employed The physician today may learn a great deal about the prognosis of this disease by turning back and looking over the rich experience of the Mediterranean Fever Commission which was recorded in 1905 to 1907 In a day when specific treatment was lacking careful clinical observations were made In an analysis of hundreds of *Br melitensis* cases Eyre stated the following in 1908

> *One may safely say that not more than 10 per cent* are convalescent in a shorter period than one month from the onset of symptoms In 50 per cent the disease extends over two months in 25 per cent to three months and in fully 15 per cent a duration of three months is exceeded

Over the succeeding years it has been observed *that a relatively small but important number* of cases will have a protracted illness Cases of bacteriologically proved brucellosis in which the disease has continued for over a year have been studied at the University of Minnesota Hospitals But such cases are not commonly encountered One cannot escape the conviction that so called chronic brucellosis is being mislabeled too often on the basis of procedures of doubtful value especially *the intradermal test with Brucella* antigen

Relapses do occur in the more chronic cases of brucellosis These recurrences are manifested by fever and by mental and physical disability with generalized aches and pains But too little attention has been given to the problem of reinfections Clinical observations in meat packing plant employees have confirmed studies made with experimentally infected animals in that the immunity induced by one attack of brucellosis is only relative Second and third infections do take place Thus in individuals who continue to be exposed to the disease it may be quite difficult to differentiate between relapses and reinfections

tious the hazards of isolating it have been over emphasized and with reasonable care accidental infection of personnel in diagnostic laboratories is unlikely

Skin test with a diluted suspension of killed *Past tularensis* or purified antigen becomes positive during the first week of disease The cutaneous response is delayed and resembles the tuberculin reaction

The total blood leukocyte count is usually normal The erythrocyte sedimentation rate is normal in ulceroglandular or mild disease but is frequently elevated in severe typhoidal tularemia

Differential Diagnosis Brucellosis typhoid fever disseminated tuberculosis the early stage of several rickettsial diseases and infectious mononucleosis can closely resemble typhoidal tularemia History of possible contacts is important and appropriate serologic and cultural studies are usually successful in differentiating these infections Pneumonic tularemia must be distinguished from viral mycotic and other bacterial infections of the lung The differential diagnosis of pneumonia is discussed in Chap 111 (p 835) Oculoglandular syndromes likely to be confused with tularemia are described in Chap 192 (p 1102)

The common ulceroglandular type of tularemia must be distinguished from a variety of infections in which a local cutaneous ulcer with regional lymphadenopathy can occur Besides ordinary pyoderma caused by streptococci or staphylococci these include lymphogranuloma venereum (p 1096) cat scratch fever (p 1098) rat bite fever (p 1019) bubonic plague (p 907) anthrax (p 913) glanders (p 911) several rickettsioses of which the important one in this country is rickettsialpox (p 1031) several viral infections of the skin such as orf cowpox etc (pp 1104 1062) and inoculation syphilis or tuberculosis In all these with the exception of lymphogranuloma venereum and cat scratch fever the regional lymph node involvement is usually proportional to the size of the cutaneous ulcer Extragenital lymphogranuloma is rare fever and systemic symptoms in cat scratch fever are rarely severe for more than a few days

Treatment Streptomycin is the antibiotic of choice for tularemia The dosage is 0 5 to 1 0 Gm every 12 hr for 7 to 10 days Response to treatment is almost invariably prompt *Pasteurella tularensis* cannot be recovered from lymph nodes or skin lesions after 24 to 48 hr of therapy However the regional lymph nodes may continue to enlarge and suppurate for several days Pulmonary lesions usually subside rapidly although the evolution of the cutaneous lesion is not interrupted The tetracycline antibiotics chloramphenicol and novobiocin are also effective although disappearance of fever and symptoms may not occur so rapidly as with streptomycin Aspiration of pus from suppurating nodes is rarely necessary if fistulas persist total surgical removal of the involved tissue can be carried out Surgery may be followed by transient recurrence of fever despite failure to demonstrate the organism in excised tissues

Prophylaxis A vaccine developed by Foshay may possibly provide protection against the occurrence of infection and definitely reduces the severity of the disease The vaccine stimulates serum agglutinins and induces positive skin reactions to the bacterial antigens Its use is recommended for hunters butchers and laboratory workers exposed to the organism Avoidance of contact with possible sources of infection is important in prophylaxis and the incidence of the disease in several localities has fallen sharply with the introduction of laws prohibiting the sale of wild rabbits by butchers

Prognosis The mortality rate in untreated tularemia is 6 to 7 per cent However with specific antimicrobial therapy death is rare A fatal outcome is more likely in typhoidal tularemia than in other types possibly because the disease may be unrecognized

Definition Human plague is an acute severe frequently fatal infection characterized by fever prostration, and suppurative lesions of the lymphatic system Sometimes there is an associated pneumonia *Pasteurella pestis* is the etiologic agent rodents are the primary hosts and the usual vectors are fleas

History Plague is one of the ancient pestilences of man Descriptions of a plaguelike disease are found in the Old Testament Early Greek and Roman manuscripts testify to its existence in the

convalescence is well under way Frequently it is overlooked or its relationship to severe systemic symptoms is not recognized Regional lymph node enlargement is a constant feature and is usually more prominent than that accompanying infections of similar severity produced by other microorganisms The involved nodes are often exquisitely tender and fluctuant The overlying skin may be hot and reddened Fistula formation and drainage can occur spontaneously Generalized lymphadenopathy *is present in some cases* but the *regional* nodes are most prominently involved There is considerable variation in the intensity of the systemic symptoms of ulceroglandular tularemia the patient may be almost asymptomatic or severely prostrated Clinical and roentgenographic evidence of pneumonitis can accompany this form of the disease illustrating its disseminated character but bacteremia is rarely demonstrable

Localized lymph node enlargement but without detectable skin lesion is referred to as *glandular* tularemia The pathogenesis of this form of the disease is probably identical to that of ulceroglandular tularemia and the features of the illness are also the same

Rarely the portal of entry of the organism is the conjunctiva where there develops an ulcer with edema congestion lacrimation photophobia and pain In this *oculoglandular* type of tularemia the preauricular submaxillary and anterior cervical lymph nodes enlarge in some patients Corneal ulceration and scarring or perforation of the globe can occur

Ingestion of contaminated meat or water can result in primary lesions of tularemia in the *gastrointestinal* tract This rare form of the disease is characterized by pronounced diarrhea abdominal pain nausea vomiting melena and hematemesis but otherwise differs little from tularemia introduced through other portals Ulcerative lesions are often found in the buccal mucosa pharynx or intestine and the mesenteric or cervical lymph nodes are involved early in the disease

Tularemia without obvious primary ulcer or localized lymphadenitis is referred to as the *typhoidal* type Constitutional symptoms in typhoidal tularemia differ in no way from those in other types of the disease although patients are as a rule more prostrated In the absence of localized manifestations the clinical recognition of tularemia is of course more difficult and diagnosis is likely to depend principally upon serologic tests or isolation of the organism

Pneumonia can accompany any of the various clinical types of tularemia Involvement of the lung is secondary to hematogenous dissemination in situations where infection is probably acquired by inhalation of the organism (as in bacteriology laboratories) there is no convincing evidence that primary tularemic pneumonia occurs Pneumonitis in tularemia can lead to prominent signs of cough mucoid sputum hemoptysis pleuritic pain dyspnea and cyanosis but extensive x ray evidence of pneumonitis is sometimes present in the absence of any symptoms of pulmonary disease Physical findings often correlate poorly with the roentgenologic changes which consist of diffuse patchy or lobar infiltrations and inconstant hilar adenopathy Pleural effusion can occur in tularemic pneumonia but lung abscess is rare

Among the unusual infections produced by *Past tularensis* are endocarditis pericarditis peritonitis appendicitis osteomyelitis and meningitis

Fever in tularemia develops abruptly often with rigors and in the untreated patient may persist at levels of 104 to 106 F for as long as 4 weeks The fever is sustained or mildly remittent and defervescence is by lysis Headache myalgia anorexia, and nausea are common

Splenomegaly of moderate degree is detectable in many patients An evanescent macular or papular *rash* is sometimes present on the trunk and extremities early in the disease

Convalescence in untreated tularemia is prolonged and fever lassitude fatigability myalgia irritability or anorexia may persist or recur for many months Recovery is usually prompt if acute tularemia is treated with antibiotics before the third week of disease When therapy is delayed beyond this period patients are more likely to be left with mild debilitation that is unresponsive to further administration of antimicrobial drugs

Recovery from tularemia is usually followed by immunity in the sense that recurrence of severe disease is unlikely However immunity to reinfection is not complete and several instances of second even third attacks of tularemia have been recorded Almost invariably they have consisted of the development of a local lesion and mild regional adenopathy without systemic symptoms and with little or no fever

Laboratory Findings Agglutinins for *Past tularensis* are present in serum after the second week of illness Although it has been said that cross agglutination may occur with antigens of *Brucella* this is by no means a constant finding

Pasteurella tularensis can be recovered from the infected patient by appropriate cultures or animal inoculation It is rarely found in blood cultures but it can be isolated from the mucocutaneous ulcer or regional lymph nodes with regularity The organism has been cultured from the sputum and gastric washings in several patients some of whom have shown no roentgenographic evidence of pneumonitis this can be a useful diagnostic procedure Although *Past tularensis* is highly infec

tious the hazards of isolating it have been over emphasized and with reasonable care accidental infection of personnel in diagnostic laboratories is unlikely

Skin test with a diluted suspension of killed *Past tularensis* or purified antigen becomes positive *during the first week of disease* The cutaneous response is "delayed and resembles the tuberculin reaction

The total blood leukocyte count is usually normal The erythrocyte sedimentation rate is normal in ulceroglandular or mild disease but is frequently elevated in severe typhoidal tularemia

Differential Diagnosis Brucellosis typhoid fever disseminated tuberculosis *the early stage* of several rickettsial diseases and *infectious mononucleosis* can closely resemble typhoidal tularemia History of possible contacts is *important* and appropriate serologic and cultural studies are usually successful in differentiating these infections Pneumonic tularemia must be distinguished from viral mycotic and other bacterial infections of the lung The differential diagnosis of pneumonia is discussed in Chap 111 (p 835) Oculoglandular syndromes likely to be confused with tularemia are described in Chap 192 (p 1102)

The common ulceroglandular type of tularemia must be distinguished from a variety of infections in which a local cutaneous ulcer with regional lymphadenopathy can occur Besides ordinary pyoderma caused by streptococci or staphylococci these include lymphogranuloma venereum (p 1096) cat scratch fever (p 1098) rat bite fever (p 1019) bubonic plague (p 907) anthrax (p 913) glanders (p 911) several rickettsioses of which the important one in this country is rickettsialpox (p 1031) several viral infections of the skin such as orf cowpox etc (pp 1101 1062) *and inoculation syphilis or tuberculosis* In all these with the exception of lymphogranuloma venereum and cat scratch fever the regional lymph node involvement is usually proportional to the size of the cutaneous ulcer Extragenital lymphogranuloma *is rare* fever and systemic symptoms in cat scratch fever are rarely severe for more than a few days

Treatment Streptomycin is the antibiotic of choice for tularemia The dosage is 0.5 to 1 0 Gm every 12 hr for 7 to 10 days Response to treatment is almost invariably prompt *Pasteurella tularensis* cannot be recovered from lymph nodes or skin lesions after 24 to 48 hr of therapy However *the regional lymph nodes may continue to* enlarge and suppurate for several days Pulmonary lesions usually subside rapidly although the evolution of the cutaneous lesion is not interrupted The tetracycline antibiotics chloramphenicol and novobiocin are also effective although disappearance of fever and symptoms may not occur so rapidly as with streptomycin Aspiration of pus from suppurating nodes is rarely necessary if fistulas persist *total surgical removal of the involved tissue* can be carried out Surgery may be followed by transient recurrence of fever despite failure to demonstrate the organism in excised tissues

Among the unusual infections produced by *Past tularensis* are endocarditis pericarditis peritonitis appendicitis osteomyelitis and meningitis

Fever in tularemia develops abruptly often with rigors and in the untreated patient may persist at levels of 104 to 106 F for as long as 4 weeks The fever is sustained or mildly remittent and defervescence is by lysis Headache myalgia anorexia and nausea are common

Splenomegaly of moderate degree is detectable in many patients An evanescent macular or papular *rash* is sometimes present on the trunk and extremities early in the disease

Convalescence in untreated tularemia is prolonged and fever lassitude fatigability myalgia *irritability or anorexia may persist or recur for* many months Recovery is usually prompt if acute tularemia is treated with antibiotics before the third week of disease When therapy *is delayed beyond* this period patients are more likely to be left with mild debilitation that is unresponsive to further administration of antimicrobial drugs

Recovery from tularemia is usually followed by immunity in the sense that recurrence of severe disease is unlikely However immunity to reinfection is not complete and several instances of second and even third attacks of tularemia have been recorded Almost invariably they have consisted of the development of a local lesion and mild regional adenopathy without systemic symptoms and with little or no fever

Laboratory Findings Agglutinins for *Past tularensis* are present in serum after the second week of illness Although it has been said that cross agglutination may occur with antigens of *Brucella* this is by no means a constant finding

Pasteurella tularensis can be recovered from the infected patient by appropriate cultures or animal inoculation It is rarely found in blood cultures but it can be isolated from the mucocutaneous ulcer or regional lymph nodes with regularity The organism has been cultured from the sputum and gastric washings in several patients some of whom have shown no roentgenographic evidence of pneumonitis this can be a useful diagnostic procedure Although *Past tularensis* is highly infec

leys radiating from these regions Sylvatic plague is dependent on other arthropod vectors and other rodent hosts and therefore has a somewhat different and wider distribution Since susceptible hosts exist in all parts of the country the appearance of this disease elsewhere is a likely possibility Vigorous rat and flea control measures have eliminated rat plague whenever it has made its appearance in American cities However sylvatic plague is impossible to eradicate and offers a constant threat of extension back to the urban rat population

Pathogenesis Following the bite of an infected flea organisms are carried by the lymphatics to the thoracic duct and thence to the blood stream There is a brief initial bacteremia during which organisms are disseminated to all the organs The chief defense of the body is the mechanism of phagocytosis aided by the development of circulating antibodies which react with the capsular substance of the organisms and thus facilitate phagocytosis Plague infection is accompanied by the production of an endotoxin which has seriously damaging effects on the tissues of the host Modern chemotherapeutic agents may result in control of the infection bacteriologically yet the patient may die from the toxemia

The most prominent lesions are ordinarily in the lymphatic system In bubonic plague a hemorrhagic zone of edema surrounds an inflamed and suppurating group of regional lymph glands The latter are hyperplastic and show areas of focal necrosis containing many organisms Similar metastatic lesions may develop in distant groups of glands or in other viscera In pulmonic infections there is a lobular pneumonia with hemorrhagic exudate in the alveolar spaces with accompanying pleuritis and bronchitis Hemorrhages may be found in any organ or beneath epithelial surfaces

Manifestations Symptoms appear after an incubation period of from 1 to 12 days The disease can assume several different clinical forms of which the *bubonic* variety is the most common Illness begins abruptly with chills a rise in temperature to 102 to 105 F tachycardia headache vomiting uncertain gait marked prostration and delirium The spleen is sometimes palpable The flea bite which represents the portal of entry rarely can be seen if present it is marked by a papule or vesicle which ultimately becomes pustular Pain and tenderness point to the regional glandular lesions which give the disease its name They are in the inguinal or femoral regions in the majority of cases less often in the axilla or neck and are uncommon elsewhere The infection may extend secondarily to other superficial or deeply situated groups of glands The bubo consists of a firm matted group of glands measuring from 2 to 5 cm in diameter and surrounded by a boggy and frequently hemorrhagic zone of edema It usually suppurates and drains spontaneously after 1 or 2 weeks though in some instances there is complete resorption

There is a marked hemorrhagic tendency presumably due to an endotoxic effect on blood vessels Petechiae or ecchymoses are often seen beneath cutaneous or mucous surfaces Bleeding may occur into a viscus or a serous cavity or from the nose alimentary respiratory or urinary tracts

The course of bubonic plague is marked by an irregular or remittent fever It often drops at the time of appearance of the bubo only to rise again In favorable cases the temperature falls gradually during the second week concomitant with improvement in the general clinical condition A rise to hyperpyrexic levels or a precipitous fall to normal or to subnormal frequently heralds approaching death Most fatalities occur during the first week of illness Though bubonic plague is usually a severe illness mild cases are sometimes seen during epidemics to these is applied the name *pestis minor*

The second clinical form of plague is the so called primary *septicemic* form which is actually a variant of bubonic plague The patient experiences a sudden and overwhelming systemic illness There is a marked constitutional reaction with chills fever rapid pulse severe headache nausea vomiting and delirium Death terminates the course within a few days before localizing lesions become clinically apparent Nevertheless autopsy usually reveals inflammation in some part of the lymphatic system

The third form which plague may take is that of *pneumonia* The initial cases appear in patients with bubonic plague of whom as many as 5 per cent develop secondary lesions in the lungs These individuals may provide the starting point for a man to man epidemiologic cycle of air borne primary pneumonic plague It is a fulminating infection accompanied by great prostration cough dyspnea and in the later stages cyanosis The sputum is abundant bloodstained and teeming with *Past pestis* Often there are no clear cut pulmonary signs though scattered rales or areas of dullness may be found In the absence of specific therapy plague pneumonia invariably ends in death within 1 to 5 days

The infectious process may localize in other regions of the body Subcutaneous abscesses and cutaneous ulcerations sometimes occur and the meninges are occasionally invaded

Laboratory Findings Since plague is an uncommon disease in the United States the diagnosis often has been overlooked until the patient has succumbed or until multiple cases have developed Nevertheless the epidemiology and the clinical

Mediterranean region long before the Christian era For many centuries the disease was endemic in Asia and in Europe where from time to time great pandemics destroyed large segments of the human population The last major outbreak originated in China in the late nineteenth century spread to all the continents and was first recognized in the United States in 1900 Some authorities believe that it was initially introduced into this country at that time through the Port of San Francisco However other evidence suggests that rodent plague actually was present long before In any event it has certainly now become well established

Etiologic Agent *Pasteurella pestis* is an encapsulated nonmotile gram negative bacterium which produces no spores and will grow under either aerobic or anaerobic conditions Though it is predominantly bacillary in shape coccal ovoid and other pleomorphic forms are often seen When stained with carbolfuchsin or carbolthionin the organisms display a characteristic bipolar appearance Growth occurs on ordinary media On agar the colonies are small round transparent colorless and viscous There are no important antigenic differences among strains collected from different animal species in various parts of the world

Epidemiology As with other infectious organisms spread through the agency of vectors *Past pestis* is enabled to survive and be transmitted by means of a series of intricate ecologic adaptations Plague is fundamentally an affection of rodents from them it is sometimes and quite incidentally transmitted to man Rats are the most important animal hosts because they are found all over the world travel widely and live in close association with man In rural or wooded regions plague may be enzootic in many other species of rodent hosts Such infection is referred to as *sylvatic plague* in contrast to *rat* or *murine plague* In the United States alone the endemic reservoir includes at least 38 species of rats mice marmots owls gophers badgers rabbits prairie dogs squirrels and chipmunks Urban plague follows a different epidemiologic pattern from rural plague Large outbreaks in man usually arise in urban areas and in the wake of rat epizootics Under circumstances of poor sanitation a concentration of people and of rats provides opportunity for the transmigration of parasites from rats to man An epizootic of sylvatic plague may encompass a number of different rodent species in an area and may involve a complex exchange of ectoparasites Such outbreaks may be devastating to the rodent populations yet they give *rise only to sporadic human cases simply because* man rarely comes into close contact with these animals Since 1900 approximately 500 cases of human plague have been reported in the United States more than *400* of these developed in association with murine plague while less than 100 resulted from contact with sylvatic plague

The flea is the usual transmitting agent In murine and human infections the most important species is the Oriental rat flea *Xenopsylla cheopis* Other arthropods occasionally function as vectors including lice ticks and possibly bedbugs The flea becomes infected by ingesting the blood of a bacteremic animal The organisms multiply in the alimentary tract of the insect and eventually plug the stomach so that no more blood can enter When the flea feeds on a new host the bite wound is inoculated by the regurgitation of organisms or as a result of mechanical contamination by the mouth parts Plague bacilli are also present in flea feces and infection may follow the scratching of this material into the skin Oriental rat fleas will accept other hosts including man particularly if rats are not immediately available When an epizootic decimates the rat population fleas are encouraged to transfer from the dead rodents to humans

Human bubonic plague results chiefly from the bite of the rat flea Infection can also be acquired by direct contact with the tissues of an infected animal or by its bite for the organisms can penetrate through skin abrasions and through intact mucous membranes Not a few accidental infections have occurred in laboratory workers as a result of handling cultures and infected animals Direct transmission of the bubonic form of the disease from man to man is unusual in contradistinction to the mode of spread of primary pneumonic plague The latter type of epidemic is initiated by a patient with bubonic disease who develops a secondary plague pneumonia and therefore excretes large quantities of organisms in his sputum The infection may then be air borne in droplet nuclei directly to a human contact This type of plague is highly contagious secondary cases are common among those attending a patient and under suitable circumstances tremendous outbreaks may occur

Plague is widely and permanently entrenched in the rodent population of the United States chiefly in the West Infected animals have been found in California Oregon Washington Utah Idaho Nevada New Mexico Arizona Texas Michigan Louisiana Florida Colorado Montana Oklahoma Kansas North Dakota and Wyoming Human cases have occurred in the first 12 of these states Recent studies emphasize the close relationship between the distribution of murine plague and that of the Oriental rat flea This flea flourishes in areas where optimal climatic conditions of mean temperature and humidity prevail In the United States these areas include the Pacific Coast region the Gulf and southern Atlantic Coast states and certain val

130 GLANDERS
Edward S Miller

Definition and Etiology Glanders is a grave infectious disorder characterized by the development of numerous granulomatous abscesses throughout the body The causative agent is *Malleomyces mallei* a small aerobic nonmotile nonsporulating gram negative bacillus

Epidemiology and Pathogenesis This is another of the group of infectious diseases of animals which are sometimes transmitted to man In this instance the principal natural hosts are horses mules and asses Glanders once was a common equine disease in America but stringent control measures have virtually eradicated it However it is still prevalent in certain sections of Central Europe North Africa and Asia The infection may be acquired by handling diseased animals Organisms gain entry through cutaneous abrasions by implantation on the conjunctiva by ingestion or by inhalation Human beings are highly susceptible as evidenced by the large number of laboratory workers who have contracted the disease With the elimination of animal glanders in the United States the infection has become rare in man also

Manifestations Human glanders usually runs an acute and stormy course After an incubation period of several days to several weeks illness begins abruptly with chills high fever and marked prostration At the portal of entry commonly on the skin a nodule forms and breaks down to become a painful ulcer Such ulcers show irregular sharply demarcated borders with little tendency to heal The regional lymph nodes are involved and lymphatic and vascular dissemination soon results in a generalized spread Miliary lesions develop along the course of lymphatics in subcutaneous and submucous tissues in muscle in the lungs and in other viscera The lesions gradually enlarge coalesce and undergo central caseous necrosis The superficial nodules ulcerate while more deeply situated abscesses often form fistulous tracts which exude discharges onto the surface Areas of consolidation appear in the lungs and the liver and the spleen become inflamed and enlarged Many patients exhibit ulcerations of the upper respiratory tract with erosion of adjacent cartilaginous and bony structures An eruption sometimes becomes evident either localized to one area or generally distributed At first it is a macular rash then it becomes papular and pustular and the lesions may ulcerate Among other septic manifestations are meningitis osteomyelitis and purulent polyarthritis Infection may extend to the sinuses ears conjunctiva mouth pharynx, and trachea

Acute glanders progresses with great rapidity ending fatally in 1 to 3 weeks in the majority of cases A milder syndrome has been described in a group of laboratory workers who were accidentally infected via the respiratory tract In these cases the clinical picture was not unlike that of viral pneumonia of average severity and all patients recovered

A chronic form of glanders sometimes is seen The onset is generally insidious with low grade fever and mild initial symptoms The course is characterized by exacerbations and remissions and punctuated by the irregular appearance of painful ulcers and draining abscesses Chronic glanders may at any time assume the fulminating qualities of the acute form More than half the patients die after months or years of exhausting illness

Diagnosis Specific diagnosis can be established by culture by animal inoculation by serologic testing by the demonstration of dermal sensitivity and by biopsy *Malleomyces mallei* can be recovered from exudates sputum scrapings from a local lesion and terminally from the blood Strauss reaction is elicited by injecting infected material into the peritoneal cavity of a male hamster or a male guinea pig Scrotal swelling becomes apparent in 2 to 4 days and organisms then can be recovered from the tunica vaginalis Both agglutinating and complement fixing antibodies appear in the blood during the second to fourth weeks of illness they are specific when present in high titer (agglutination titer of 1 640 or higher complement fixing titer of 1 20 or higher) except for some cross reaction with the antigens of *Malleomyces pseudomallei* The latter organism causes melioidosis a disease closely related to glanders (see p 912) Patients who survive the initial onslaught of illness develop a persistent skin sensitivity to mallein which is an antigen prepared from cultures of *M mallei* The test is performed by intradermal injection of 0 1 ml of a 1 10 000 dilution of commercial mallein it is considered positive if an erythema is present 48 hr later Skin and mucous membrane lesions show characteristic histologic features and are readily accessible to biopsy

Treatment Sulfadiazine has proved to be a potent chemotherapeutic agent in experimental animal infections and has been used successfully in several human cases The drug should be administered for a minimum of 20 days in doses sufficient to maintain blood levels of 10 to 15 mg per 100 ml Penicillin is ineffectual Streptomycin was of only slight benefit in an experimental study but appeared to be useful in the treatment of one reported human case Little or no information is available on the therapeutic activity of the newer antibiotics It is evident that strains isolated from

features provide highly characteristic leads to the clinician Once a suspicion of plague is entertained it can readily be verified by smear culture and animal inoculation of appropriate specimens If a bubo is present a small quantity of interstitial fluid should be aspirated from its center Large numbers of morphologically characteristic bacilli are usually seen in a stained smear Infected sputum likewise contains many organisms Bacteremia of varying degrees occurs at some time during the course of nearly all cases Pus and sputum should be cultured on blood agar plates while blood is inoculated into hormone cystine or other nutrient broth Organisms are identified by their morphologic and colonial characteristics and by agglutination with specific antiserum Guinea pig inoculation is the final step in identification In this animal the gross and micro scopic lesions are highly characteristic It is to be emphasized that the handling of infected materials or animals involves great danger of infection of the laboratory workers Except as mentioned above serologic tests have not been satisfactory or useful in diagnosis

The white blood cell count is elevated to levels of 20 000 to 40 000 with a predominance of poly morphonuclear leukocytes There is little or no change in the red blood corpuscles

Differential Diagnosis Before the appearance of localizing signs plague may be confused with severe systemic illnesses such as typhoid or typhus The bubonic form bears certain resemblances to other varieties of infectious lymphadenitis includ ing tularemia syphilis and lymphogranuloma venereum and to those of staphylococcal or strep tococcal origin Pneumonic plague must be distin guished from tularemic pneumococcal and other bacterial pneumonias as well as from psittacosis and primary atypical pneumonia A consideration of epidemiologic factors plus bacteriologic studies will aid in the differentiation

Treatment The therapy and the prognosis of plague have been vastly improved by the intro duction of streptomycin and other chemothera peutic agents Even pneumonic and septicemic cases can be salvaged *if treatment is initiated early* (within the first 20 hr after onset) Streptomycin is the drug of choice it is given in divided doses of 2 to 4 Gm daily until the patient has been *afebrile at least 3 days* Sulfadiazine is almost as effective in uncomplicated bubonic plague but definitely less so in septicemic and pneumonic cases Chloramphenicol oxytetracycline chlortetracycline neomycin and polymyxin are all potent antiplague substances the first two have been used success fully in treating pneumonic plague Antiplague serum also has value as an antitoxic agent Various combinations of these medicines can be used to advantage depending on their availability the severity of illness and the duration of illness before treatment is begun

Buboes are treated with hot moist applications Incision and drainage should be postponed until the lesion becomes well localized

Prophylaxis and Control The control of plague in endemic urban areas demands unceasing vigi lance in detecting rodent epizootics and vigorous measures in combating outbreaks The most im portant control measures are those aimed at ex termination of rats and their ectoparasites Rats are attacked by poisoning and trapping by elimination of harborage areas and by separating them from their food supplies DDT has been used with bril liant success in diminishing the flea population in festing both rodents and human beings thereby interrupting the rat flea rat and the rat flea man cycles of transmission

The elimination of sylvatic plague is an impos sible task For protection of the individual reliance must be placed on avoidance of contact with wild rodents For protection of a community within an endemic area it is essential to eradicate rodents within the city and to maintain a rodent free belt surrounding it

Patients must be disinfested and carefully iso lated while other intimately exposed persons should be quarantined Excellent prophylaxis is provided by administering sulfadiazine to contacts in a dose of 3 Gm a day this often protects even against ex posure to pneumonic patients Two types of bac terial vaccines are in use one composed of dead organisms and the other containing a special aviru lent strain of living bacilli Both provide limited and transitory active immunity General vaccina tion of a population is a *worthwhile procedure in* an area under threat of an epidemic

Prognosis Formerly the fatality rate of bubonic plague averaged 50 to 90 per cent while the *pneumonic septicemic and meningitic forms* were almost invariably fatal However even the gravest varieties of infection respond to chemotherapy The over all fatality rate has been reduced to 5 to *10 per cent.*

132 ANTHRAX

Leighton E Cluff and
Ivan L Bennett Jr

Definition Anthrax (malignant pustule charbon, splenic fever milzbrand woolsorters disease) is a disease of wild and domesticated animals that is transmitted to man by contact with infected animals or their products and rarely by insect vectors which act as mechanical carriers of the etiologic organism The characteristic lesion of human anthrax is a necrotic cutaneous ulcer the malignant pustule"

Etiology *Bacillus anthracis* is a large encapsulated gram positive aerobic spore forming microorganism that grows well in most nutrient media Its pathogenicity for laboratory animals differentiates it from *Bacillus subtilis* which it closely resembles The spores are killed by boiling for 10 min but can survive for many years in soil and in animal products an important factor in persistence and spread of the disease The bacillus was identified by Royer and Davaine in sheep in 1849 and was therefore the first causative agent of an infectious disease ever demonstrated The classic studies of Robert Koch in 1877 showing that *B anthracis* was indeed the cause of anthrax serve as the prototype for the establishment of etiology of infectious diseases

Epidemiology Anthrax is world wide repeated outbreaks have occurred in Southern Europe Africa Australia Asia and on both American continents

Cattle horses sheep goats and swine are most commonly infected Between 1945 and 1955 there were 3 447 recognized outbreaks of anthrax among animals in the United States centering mostly in South Dakota Nebraska Arkansas Mississippi Louisiana Texas and California The tendency of the disease to occur in animals in late summer and early fall is related to grazing conditions and the abundance of flies

The disease in man is acquired by butchering skinning or dissecting infected carcasses or by handling contaminated hide wool hair or other materials It is seen principally in agricultural and industrial employees Of the 183 reported cases of human anthrax in this country between 1945 and 1955 the majority involved workers handling imported and unprocessed wool hair or hides The usual form of human disease follows inoculation of bacilli or spores into the skin often, if not always through a wound or abrasion However intestinal infection has followed ingestion of contaminated meat and anthrax has been thought to develop after inhalation of spores

Pathogenesis The "malignant pustule" which follows cutaneous inoculation of anthrax organisms is characterized microscopically by vesiculation neutrophilic infiltration and gelatinous edema in surrounding structures Suppuration is rare in the absence of secondary pyogenic infection Spread of the bacilli to the regional lymph nodes may be followed by systemic dissemination Examination of tissues from fatal human cases reveals masses of the bacteria in blood vessels lymph nodes parenchyma of various organs and in connective tissues There is scanty or absent cellular exudation at these foci the predominant changes being widespread hemorrhage and edema So-called anthrax pneumonia" and "anthrax meningitis are in all probability an expression of this generalized hemorrhage and edema in an easily detectable clinical site rather than selective localization of bacterial multiplication in these tissues

Although it was at one time thought that in anthrax death might be the result of occlusion of vessels by masses of bacilli studies have now shown that the blood of fatally infected experimental animals contains a lethal toxin which can be neutralized by appropriately prepared antiserums This toxin has not been isolated with regularity in vitro and its exact role in the pathogenesis of the disease requires further study

Manifestations The malignant pustule" of human anthrax begins usually on an exposed body surface as a painless pruritic erythematous papule which soon vesiculates and ulcerates to form a black eschar Tiny satellite vesicles are frequent The ulcer may be surrounded by extensive edematous swelling which is nontender nonpitting and so characteristic of anthrax that it is a valuable diagnostic sign After about 5 days the ulcer begins to subside but edema may persist for many days or even weeks Mild tenderness and enlargement of regional lymph nodes is frequently present but the involvement is not so striking as in tularemia or cat scratch disease Constitutional symptoms are often absent despite extensive local changes but there may be mild fever headache and malaise In the infrequent fulminant case of disseminated anthrax high fever prostration and a rapidly fatal course are seen So called woolsorters disease" a highly fatal disseminated infection is

patients should be subjected to careful studies of in vitro sensitivities and treatment should be guided thereby Other antibiotics singly or in combination may prove even more effective than sulfadiazine

131 MELIOIDOSIS

Edward S Miller

Definition Melioidosis is a fulminating usually fatal infectious disease in which granulomatous lesions develop throughout the body Etiologically pathologically and clinically it bears a striking resemblance to glanders

Etiology The causative organism is *Malleomyces pseudomallei* a motile aerobic gram negative bacillus This bacterium is closely related to *Malleomyces mallei* the causative agent of glanders but the two can be differentiated by bacteriologic and serologic methods There is also an important epidemiologic difference for the primary hosts and principal reservoir of melioidosis are rats whereas glanders is chiefly an affection of horses The mode of transmission has not been established but is believed to occur via contamination of food and water with the excreta of infected rodents the portal of entry being the alimentary tract

Epidemiology The disease was first identified in Rangoon in 1911 and some 300 cases have since been observed in Indo China the Malay States Thailand Ceylon and contiguous regions It may have a broader geographic distribution than has heretofore been suspected for cases have been reported as originating in Guam and in the United States

Manifestations The clinical course of melioidosis is much like glanders except that it is even more virulent and lethal Nearly all untreated cases have ended fatally *In the most acute form illness is sudden in onset with shaking chills high fever* and marked prostration often associated with vomiting and severe diarrhea Bacteremia occurs early and results in the development of widely disseminated *granulomatous abscesses The patient* passes into a state of stupor or coma and dies within 3 to 14 days In subacute cases the course of disease is similar except that the patient survives sufficiently long (3 to 4 weeks) for some of the disseminated *lesions to become clinically evident* These are likely to develop in the skin subcutaneous tissues muscles lungs bones liver and spleen Pyelonephritis orchitis epididymitis and prostatitis sometimes are seen A pustular rash has been observed *In rare cases melioidosis becomes chronic* with deep seated lesions and draining sinuses *which persist for years*

Diagnosis Cultural methods afford the best means of prompt diagnosis for *M pseudomallei* can be recovered readily from blood sputum exudates and urine As in glanders Strauss reaction can be elicited by intraperitoneal injection of infected material into male hamsters and guinea pigs The agglutination and complement fixation tests become positive after 2 to 4 weeks Biopsy specimens reveal characteristic pathologic changes indistinguishable from those seen in glanders

Treatment The reported fatality rate of 95 per cent attests to the inefficacy of older methods of treatment Experimental studies indicate that various sulfonamides oxytetracycline and chloramphenicol may be effective against the organism whereas it is resistant to penicillin streptomycin chlortetracycline and polymyxin Scattered reports indicate beneficial clinical results from the use of chloramphenicol chlortetracycline and various sulfonamides There evidently is wide variation in strain susceptibility so it is imperative that clinical treatment be controlled by in vitro sensitivity tests

the ingestion of contaminated milk. The names *Haverhill fever* and *erythema arthriticum epidemicum* have been applied to cases in which there was no history of rat bite The clinical picture is the same in both types of infection.

Manifestations The incubation period is comparatively short The interval between the rat bite and the development of symptoms is usually 3 to 7 days while in the Haverhill epidemic the incubation period appeared to be only 1 to 3 days The onset of symptoms is sudden, with malaise and fever headache and vomiting About half the patients have one chill or more The temperature course is quite variable usually there is an intermittent or remittent type of fever Occasionally the fever is relapsing in type *Arthritis* usually appears during the first week of the disease and involves one or more of the larger joints which become hot swollen and tender In addition, there are generalized muscle aches A *skin eruption* appears in over 90 per cent of cases This is usually most prominent on the extremities in the vicinity of joints and consists of reddened flat papules 1 to 4 mm in diameter When infection has been acquired by rat bite there are usually signs of mild inflammation at the site and regional lymph nodes may be enlarged and tender

Bacterial endocarditis is a rare but serious complication of this infection

The natural duration of the disease is variable It may subside after a few days or it may persist for several weeks Recovery is the rule even without specific treatment and permanent disability due to joint involvement seldom occurs

Laboratory Findings A moderate leukocytosis with a leukocyte count of 10 000 to 15 000 is often observed although the leukocyte count remains normal in some cases A specific diagnosis is made by isolation of the causative organism from the blood or from joint fluid Growth is usually visible after 48 hr as small puffball" colonies at the bottom of the flask of liquid medium These show the characteristic pleomorphic configuration Agglutinins for *Streptobacillus moniliformis* can be demonstrated in the blood after the second week of disease

Differential Diagnosis In patients with a history of rat bite the principal difficulty is in differentiating *Streptobacillus moniliformis* from *Spirillum minus* infection. The clinical features of the two diseases may be very similar and positive diagnosis can be made only by demonstration of the causative organism in the patient s blood A tentative diagnosis of *Streptobacillus moniliformis* infection may be based on a short incubation period, prominence of joint symptoms and failure to respond to arsenical therapy Where there is no history of rat bite differentiation from such diseases as rheumatic fever chronic meningococcemia and malaria must be made

Treatment Penicillin is an effective agent in the treatment of *Streptobacillus moniliformis* infection A dose of 400 000 units a day should produce clinical improvement within 48 hr Treatment should be continued for about a week.

Prognosis This infection is always benign unless complicated by other illnesses

134 BARTONELLOSIS

W Elizabeth Gambrell

Definition Bartonellosis or Carrion s disease is an infection with *Bartonella bacilliformis* a small pleomorphic bacillus found in close association with the red blood cells and transmitted by certain species of sandfly of the genus *Phlebotomus* Two well-defined clinical types may develop—an acute febrile anemia of rapid onset and high mortality designated *Oroya fever* and a benign eruptive form with cutaneous lesions of fairly long duration called *verruga peruana* Either of these types may be mild in some individuals with an asymptomatic invasion of erythrocytes by the organism These cases constitute the greatest epidemiologic hazard

Etiology *Bartonella bacilliformis* is a small motile pleomorphic gram negative bacillus which stains reddish violet with Giemsa s stain. It can be cultured on enriched media and chick embryos

Epidemiology The disease is limited geographically to certain valleys in the Andes chain of mountains in South America, comprising parts of Peru, Ecuador and Colombia It occurs in regions between the altitudes of 2 400 and 8 000 ft where the insect vector *Phlebotomus* propagates The reservoir of infection is not known, but certain plants and lower animals have been suspected since the disease is often contracted in regions which are practically uninhabited Epidemics occur more frequently during the rainy season and often co-

characterized by cyanosis dyspnea and hemoptysis and has been thought to result from inhalation of the spores It has not been established that this type of infection is dependent upon the pulmonary route of inoculation As has been mentioned human infection can occur from ingestion of the uncooked meat of infected animals However enormous numbers of organisms are probably necessary to produce the disease by this route in man and it does not occur in the United States

Laboratory Findings The serosanguineous fluid from the cutaneous lesion frequently contains many bacilli demonstrable by Gram s stain and culture Bacilli may be found on direct examination or culture of the blood of patients with bacteremia The blood leukocyte count is normal in mild cases but there is polymorphonuclear leukocytosis in severe disease Similarly the erythrocyte sedimentation rate may be increased but changes are irregular There are no characteristic abnormalities of the urine Patients with meningeal involvement usually show bloody spinal fluid in which the organisms are easily found by direct examination or culture

Diagnosis A positive diagnosis of anthrax can be made by isolation of the organism in culture However a history of occupational exposure and the characteristic eschar and edema should suggest the proper diagnosis Pyogenic infections of the skin are usually painful whereas the malignant pustule" is not. In addition cutaneous anthrax is rarely purulent The differential diagnosis of other diseases characterized by local ulceration at the portal of entry is discussed in Chap 128 (p 907)

Treatment and Prophylaxis Many antibiotics are effective in the treatment of human anthrax including penicillin chloramphenicol (Chloromycetin) tetracycline derivatives erythromycin and streptomycin Six hundred thousand units of aqueous crystalline or repository penicillin should be given once or twice daily until the local edema subsides The eschar goes through its natural evolution in spite of treatment and lymph node enlargement may persist for several days *Bacillus anthracis* cannot be recovered from the skin lesion after 24 to 48 hr of penicillin therapy but it may persist for a longer period when chloramphenicol or tetracycline is used

Exposure of personnel in industrial plants where contaminated animal products are handled still occurs in spite of measures to control it Sterilization of all raw wool mohair etc would probably remove this hazard but has had only limited application Transmission of anthrax from one human being to another has never been recognized Whereas the disease was fatal in 20 to 30 per cent of cases before specific antimicrobial drugs were available the mortality is now less than 1 per cent in the United States

A vaccine prepared from the protective" antigen of *B anthracis* is available but its effectiveness in man has not been fully evaluated Spore vaccines of various types are used with good effect in domestic animals in endemic areas

133 *STREPTOBACILLUS MONILIFORMIS* INFECTION

Paul B Beeson

Definition This is an acute infectious disease caused by *Streptobacillus moniliformis* and characterized by fever arthritis and skin eruption When the mode of infection is the bite of a rat this disease is sometimes called *rat bite fever*

Etiology The causative organism is a pleomorphic microorganism which grows in chains with beadlike structures interposed It stains irregularly by Gram s method and is more easily demonstrated with Giemsa or Wayson methods This organism is regarded by some workers as a fungus because of its morphologic appearance and is sometimes called *Actinomyces muris* or *Streptothrix muris ratti* The L_1 pleuropneumonia like microorganism of Klieneberger has often been found in association with it but there is dispute as to whether the relationship between them is that of symbiosis or variation in morphology *Streptobacillus moniliformis* grows readily in liquid cultures enriched with blood or ascitic fluid The organism is pathogenic for mice in which it may cause acute polyarthritis

Epidemiology *Streptobacillus moniliformis* infection may be acquired in two different ways Nearly all sporadic cases result from the bites of rats These are most common in infants and children and in laboratory workers The other type of infection occurs in epidemics One such epidemic occurred in Haverhill Mass another in Chester Pa both were thought to have been caused by

uncommon Systemic complications of granuloma inguinale (such as invasion of the bones joints and viscera) have also been noted suggesting that the infecting agent can spread throughout the body by way of the blood stream

Clinical Manifestations The lesion of granuloma inguinale usually is a painless sharply demarcated ulcer having an exuberant red granulating base which bleeds easily on trauma The disease is extremely chronic and the ulcers slowly enlarge and coalesce Secondary infection frequently is present and produces a foul smelling seropurulent discharge Interference with lymphatic drainage may occur leading to swelling and elephantiasis of the genitalia similar to that caused by lymphogranuloma venereum When healing occurs further scarring and deformity may appear Lesions of the cervix of the uterus are frequent and sometimes are mistaken for carcinoma Lesions about the perianal area closely resemble condylomata lata of secondary syphilis and dark field examinations and serologic tests for syphilis are often necessary to differentiate the two conditions

The disease occasionally produces widespread manifestations such as arthritis and osteomyelitis In such instances there may be general debility anemia and malnutrition occasionally these have resulted in death

Diagnosis The diagnosis of granuloma inguinale is based upon demonstration of the presence of Donovan bodies Impression smears of early lesions stained by Wright s method usually will show Donovan bodies lying within the cytoplasm of large mononuclear cells The smear is of less value in chronic cases The diagnosis can also be made by histologic examination of fixed tissues The microscopic appearance of granuloma inguinale is essentially that of a richly vascularized granulation tissue with marked inflammatory cell infiltration Polymorphonuclear leukocytes are scattered throughout the tissue and form small microabscesses Numerous large mononuclear cells are also present and show finely reticulated or vacuolated cytoplasm Phagocytosis of polymorphonuclear leukocytes and other cellular debris by these cells is common Intracellular or extracellular Donovan bodies are readily seen in tissue sections particularly in acute cases In chronic cases they may be found only after considerable search but the histologic pattern is sufficiently characteristic to permit a tentative diagnosis even when organisms are not found Specific serologic tests (complement fixation) and skin tests have been developed but their diagnostic value is yet to be determined

Treatment Healing of granuloma inguinale will usually occur promptly following treatment with streptomycin chloramphenicol or the tetracyclines Streptomycin has the disadvantage of requiring parenteral administration The other antibiotics *seem to be more effective and are given orally* in doses of 2 Gm a day for approximately fifteen days These antibiotics have treponemicidal properties and should not be given until repeated dark field examinations and serologic tests have excluded the diagnosis of early syphilis

136 *LISTERIA* AND *ERYSIPELOTHRIX* INFECTIONS

Paul D Hoeprich

History *Listeria* was isolated from a case of meningitis in 1918 but it was not recognized as a species until 1926 following isolation from a laboratory epizootic A succession of names followed until *Listeria monocytogenes* was accepted in 1940 Since then the many traits common to both *Listeria* and *Erysipelothrix* have led to the meritorious suggestion that but one generic name *Erysipelothrix* be used

Erysipelothrix infection in humans was described in 1884 when the name *erysipeloid* was advanced for the unique skin disease produced by this organism

Etiology *Listeria* and *Erysipelothrix* are gram positive nonsporulating microaerophilic bacilli *Listeria* is motile *Erysipelothrix* is not but neither can be identified solely on morphologic or cultural grounds Both organisms are readily and frequently confused with nontoxigenic *Corynebacteria* and occasionally with *Streptococci* Antigenic distinction is clearly drawn even to the point of distinguishing four types of *Listeria* unfortunately serums are not commonly available for laboratory diagnosis Accordingly suggestive morphologic and

incide with immigration of workers from uninfected areas

Manifestations The incubation period is approximately 3 weeks but may be longer The initial symptoms are fever and pains in the bones joints and muscles In the early stages the disease often resembles influenza or malaria but blood cultures for *Bartonella* are positive even in the absence of anemia Following this initial stage the patient develops in days or months one of the two classic types of the infection

Oroya Fever

This type is characterized by sudden onset of high fever extreme pallor weakness and a precipitous drop in the red blood cells The count may fall from normal to 1 million per milliliter in 4 or 5 days Muscle and joint pain is severe and headache insomnia delirium and coma are the terminal manifestations Death may occur within 10 days to 4 weeks Organisms are numerous in the blood and stained smears may show 90 per cent of the erythrocytes heavily invaded They are also present in the circulating monocytes and fixed phagocytes of the reticuloendothelial system Secondary bacterial infection particularly with *Salmonella* is an important factor in fatal cases Neither hemolysins nor agglutinins for *Bartonella* are found in the serum of patients Recovery results if the organisms decrease and fever abates The red cell count stabilizes then approaches normal values in about 6 weeks when convalescence begins

Verruga Peruana

This form of the disease characterized by a profuse skin eruption may follow the anemic form or may occur in patients without previous symptoms The verrugas vary in color from red to purple and vary in size and location They may be miliary nodular or eroding and they range in size from 2 to 10 mm up to 3 or 4 cm in diameter The three types of verrugas may occur together since eruption takes place in successive crops verrugas of all types and all stages of development may be found on the same patient The chief sites involved are the limbs and face and less frequently the genitalia scalp and mucosa of the mouth and pharynx They may persist from 1 month to 2 years The eruption is accompanied by pain fever and moderate anemia *Bartonella* may be demonstrated in the lesions and cultured from the blood

Treatment Recently antibiotics have proved very effective against the infection Results with penicillin in the anemic phase are spectacular but streptomycin has proved more efficacious in the eruptive phase Choramphenicol orally or intravenously is highly effective particularly when *Salmonella* infections are also present

135 GRANULOMA INGUINALE

Albert Heyman

Definition Granuloma inguinale is a chronic ulcerative granulomatous disease usually confined to the skin and mucous membranes of the genito inguinal area but occasionally appearing in other portions of the body

Etiology The etiologic agent of this disease is the Donovan body a nonmotile gram negative bacillus In stained smears of the lesions the organisms appear as encapsulated bipolar bodies situated within large mononuclear cells In chick embryo cultures the morphology of the organism is variable and may consist of bipolar forms curved rods chains or unencapsulated bodies The organism is not pathogenic for laboratory animals and can be cultivated only in artificial media containing yolk material

Incidence Granuloma inguinale was once regarded as occurring only in tropical or subtropical areas but it has been shown to exist in almost every country and climate The majority of the cases in the United States are found in the Southeastern section usually among Negroes The incidence of the disease has decreased significantly in this country during recent years Approximately six hundred cases were reported in 1955

Pathogenesis Granuloma inguinale is generally believed to be acquired by sexual intercourse The disease is apparently not highly infectious however since it is frequently not transmitted to sexual partners The factors predisposing to invasion of the organism are not definitely known but the disease is found most frequently among sexually promiscuous individuals and in association with other venereal diseases The incubation period varies from 3 to 40 days Although the majority of infections appear on or near the external genitalia lesions about the face hands and neck are not

lating antibody disappears during the months following cure of *Listeria* infections There is no clinical evidence to indicate whether or not this augurs return to preinfection susceptibility With erysipeloid second attacks have been reported although these have been associated with different sources

Section 7 Diseases Due to Toxin-producing Bacteria

137 DIPHTHERIA

Paul B Beeson

Definition Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae* characterized by a local inflammatory lesion usually in the upper respiratory passages and by distant effects particularly on the heart and peripheral nerves due to specific exotoxin

History The first accurate description of the disease was given by Bretonneau in 1826 In 1883 Klebs described the morphologic appearance of *C diphtheriae* in stained preparations from diphtheritic membranes A year later Loeffler isolated the organism in pure culture and showed that it was capable of producing lesions resembling those of human diphtheria in experimental animals In 1888 Roux and Yersin showed that some of the manifestations of diphtheria in guinea pigs could be produced by sterile filtrates of *C diphtheriae* cultures By 1893 von Behring had demonstrated the neutralizing effect of antiserum on diphtheria toxin in experimental animals this was soon followed by the treatment of human diphtheria with antitoxin Schick described the skin test for susceptibility to diphtheria in 1913 Ramon in 1923 showed that the toxin could be altered in such a way as to render it noninjurious without destroying its antigenic property (toxoid) this was the basis for present methods of active immunization against diphtheria

Etiology *Corynebacterium diphtheriae* is a gram positive pleomorphic unevenly staining bacillus Three principal types are recognized *mitis intermedius* and *gravis* These types are distinguished by the appearance of their colonies on tellurite medium and by their capacity to ferment glycogen and dextrose European workers particularly those in the British Isles believe that there is a significant difference in the clinical manifestations of diphtheria produced by the different varieties gravis and intermedius diphtheria being associated with *severe toxic manifestations whereas the chief* danger of mitis diphtheria is laryngeal obstruction In the United States the gravis type is comparatively uncommon and less significance is attached to the relationship of the type of organism to the clinical form of the illness

The exotoxin produced by *C diphtheriae* is a potent poison having the chemical properties of a protein In highly purified preparations the minimum lethal dose for guinea pigs is as little as 0 0001 mg

Epidemiology Diphtheria can occur at any age but is most frequently encountered in children between the ages of two and five years There is no marked difference in sex incidence The principal mode of transmission is apparently by droplet infection especially from asymptomatic carriers Fomites probably play little part in the spread of diphtheria but *C diphtheriae* can remain alive and virulent in dust of a darkened room for several weeks This could serve as a means of spread of the infection It has been discovered that bacteriophage can effect a change whereby an avirulent form of *C diphtheriae* is converted to a virulent toxin producing form This may be of great significance in explaining the mysterious sudden appearance of virulent strains in populations previously free of them

Pathogenesis In the majority of cases the growth of diphtheria bacilli is confined to a superficial area there being little tendency for the organisms to invade deeper tissues or to enter the lymphatics or blood stream except in terminal stages of the disease The exotoxin produced by bacilli in the local lesion is however carried by the blood to all parts of the body Dissemination of this toxin with damage to remote areas appears to be greater

cultural data must be reinforced by demonstration of pathogenicity in animals

Swabbing the conjunctiva of the rabbit with *Listeria* regularly leads to a keratoconjunctivitis in 3 to 5 days The process usually remains localized to the eye and is caused by no other organism save rare strains of *Erysipelothrix* Generalized infection of the rabbit with either *Listeria* or *Erysipelothrix* provokes a monocytosis this reaction is more pronounced with *Listeria* Both organisms cause lethal disease on intraperitoneal inoculation of the mouse *Listeria* producing pinhead sized foci of hepatic necrosis *Erysipelothrix* giving rise to a severe conjunctivitis In general *Listeria* localizes in the meninges myocardium or liver *Erysipelothrix* lodges preferentially in skin endocardium or joints

Epidemiology and Pathogenesis Both organisms are widespread in nature where they appear to be primarily parasites causing disease in man and in a variety of birds and animals both wild and domestic It is presumed that wildlife comprises a major reservoir however a mechanism making for sporadic disease is obscure Infection in man is a dead end since transmission from human to human (except transplacental with *Listeria*) has never been proved The gastrointestinal tract has been postulated as the most likely route of entry for *Listeria*

Erysipelothrix apparently gains foothold through injuries to the skin and so is frequently an occupational disease The incidence of erysipeloid parallels the incidence of swine erysipelas in being highest in summer and early fall In this connection isolation of *Erysipelothrix* from flies may be pertinent

Manifestations Generally human disease caused by *Listeria* is not clinically unique *Listeria* however has recently been shown to be the cause of miliary granulomatosis Described as a pathologic entity in 1893 this disease was found in certain aborted premature stillborn and neonatal children Its onset in the mother may be entirely asymptomatic although more commonly a week to a month ante partum there has been malaise followed by a shaking chill perhaps associated with pains in the back or flanks The disease is benign and self limited in the mother and as these symptoms spontaneously disappear fetal movement diminishes or stops Infection of the fetus may take place as early as the fifth month of gestation delivery is normal though before term Fetal infection is usually lethal ante partum Of those children born alive most succumb within minutes post partum while the remainder usually do not survive beyond 2 weeks

Meningitis is by far the most common clinical form of human *Listeria* infection In a recent monograph Seeliger tabulated 291 cases of bacteriologically proved listerosis 87 involved the central nervous system Clinically meningitis due to *L monocytogenes* cannot be distinguished from meningitis due to other bacteria

Other syndromes caused by *Listeria* but exceedingly rare in occurrence include a generalized illness with high fever subacute bacterial endocarditis polyserositis and an oculoglandular disease

While *Erysipelothrix* may rarely cause endocarditis an intestinal and generalized disease in human beings *cutaneous infection is relatively common* Of 2 300 infected hands seen by King in a 4½ year period 115 were erysipeloid It is almost restricted to persons who in their occupations handle animals fish shellfish or materials derived from animals or dead matter of plant or animal origin Two to seven days after injury the typical lesion surrounds the site of entry This is a maculopapular nonvesiculated sharply defined purplish red zone which is accompanied by a feeling of heat burning irritation and pain There is some swelling and nearby joints become stiff By 3 to 5 days after injury centrifugal spread of the rash is definite Movement is slow and by 1 week the central portion of the lesion has healed and may be desquamating Local symptoms subside as healing occurs *There is no fever and general symptoms are uncommon* Regional lymphangitis and lymphadenitis nausea and vomiting rarely are seen

Laboratory Findings Both *Listeria* and *Erysipelothrix* grow well on the usual laboratory media Recognition of their significance when cultured usually depends on their being distinguished from diphtheroids Monocytosis is not commonly found Other laboratory findings are in keeping with the clinical syndromes engendered

Differential Diagnosis With the exception of miliary granulomatosis there is no clinical basis for singling out *Listeria* as cause of an infection Reports of diphtheroids or no pathogens in cultures from cases of clinical infection suggest *Listeria*

The appearance of erysipeloid its slow and limited spread the lack of constitutional reaction the history of occupation and injury all serve to identify this disease *Erysipelothrix* may be recovered by culture of tissue taken in biopsy of a lesion or more simply by culture of saline injected and aspirated at the periphery of a lesion

Treatment Both *Listeria* and *Erysipelothrix* are susceptible to the action of penicillin the tetracyclines chloramphenicol erythromycin and novobiocin The agent of choice is penicillin General supportive measures should be used as indicated and local therapy such as drainage carried out as needed

Prognosis Prompt antibiotic therapy is highly effective On the basis of agglutinin titers circu

lating antibody disappears during the months following cure of *Listeria* infections There is no clinical evidence to indicate whether or not this augurs return to preinfection susceptibility With erysipeloid second attacks have been reported although these have been associated with different sources

137 DIPHTHERIA

Paul B Beeson

Definition Diptheria is an acute infectious disease caused by *Corynebacterium diphtheriae* characterized by a local inflammatory lesion usually in the upper respiratory passages and by distant effects particularly on the heart and peripheral nerves due to specific exotoxin

History The first accurate description of the disease was given by Bretonneau in 1826 In 1883 Klebs described the morphologic appearance of *C diphtheriae* in stained preparations from diphtheritic membranes A year later Loeffler isolated the organism in pure culture and showed that it was capable of producing lesions resembling those of human diphtheria in experimental animals In 1888 Roux and Yersin showed that some of the manifestations of diphtheria in guinea pigs could be produced by sterile filtrates of *C diphtheriae* cultures By 1893 von Behring had demonstrated the neutralizing effect of antiserum on diphtheria toxin in experimental animals this was soon followed by the treatment of human diphtheria with antitoxin Schick described the skin test for susceptibility to diphtheria in 1913 Ramon in 1923 showed that the toxin could be altered in such a way as to render it noninjurious without destroying its antigenic property (toxoid) thus was the basis for present methods of active immunization against diphtheria

Etiology *Corynebacterium diphtheriae* is a gram positive pleomorphic unevenly staining bacillus Three principal types are recognized *mitis intermedius* and *gravis* These types are distinguished by the appearance of their colonies on tellurite medium and by their capacity to ferment glycogen and dextrose European workers particularly those in the British Isles believe that there is a significant difference in the clinical manifestations of diphtheria produced by the different varieties gravis and intermedius diphtheria being associated with severe toxic manifestations whereas the chief danger of mitis diphtheria is laryngeal obstruction In the United States the gravis type is comparatively uncommon and less significance is attached to the relationship of the type of organism to the clinical form of the illness

The exotoxin produced by *C diphtheriae* is a potent poison having the chemical properties of a protein In highly purified preparations the minimum lethal dose for guinea pigs is as little as 0 0001 mg

Epidemiology Diphtheria can occur at any age but is most frequently encountered in children between the ages of two and five years There is no marked difference in sex incidence The principal mode of transmission is apparently by droplet infection especially from asymptomatic carriers Fomites probably play little part in the spread of diphtheria but *C diphtheriae* can remain alive and virulent in dust of a darkened room for several weeks This could serve as a means of spread of the infection It has been discovered that bacteriophage can effect a change whereby an avirulent form of *C diphtheriae* is converted to a virulent toxin producing form This may be of great significance in explaining the mysterious sudden appearance of virulent strains in populations previously free of them

Pathogenesis In the majority of cases the growth of diphtheria bacilli is confined to a superficial area there being little tendency for the organisms to invade deeper tissues or to enter the lymphatics or blood stream except in terminal stages of the disease The exotoxin produced by bacilli in the local lesion is however carried by the blood to all parts of the body Dissemination of this toxin with damage to remote areas appears to be greater

when the primary lesion is in the nasopharynx and less when it is in other sites such as the larynx or on the anterior nasal mucosa

The *primary lesion* of diphtheria is a superficial ulceration covered by a membrane It is most often located on the mucosal surface of the tonsils uvula soft palate nasopharynx nose larynx trachea or bronchi The membrane consists of a coherent mass of bacteria necrotic epithelium phagocytes and fibrin and is firmly attached to the underlying tissues The deeper tissues become intensely congested and edematous There is acute inflammation of the regional lymph nodes which are packed with phagocytes and necrotic material

In addition to the local lesion morphologic changes may be found in many tissues after death from diphtheria *Peripheral nerves* show degenerative changes in the medullary sheaths less commonly there is degeneration of the axis cylinders The *heart* is often dilated there may be cloudy swelling and hyaline changes in the myocardium Cloudy swelling is nearly always present in the *kidney* *Petechial hemorrhages* are occasionally found in the kidneys skin and adrenal glands

Death in diphtheria may result from respiratory obstruction due to the membrane and edema or it may be caused by the action of the toxin on the heart nervous tissue and other organs The mechanism of circulatory failure in diphtheria has been the subject of some controversy Unquestionably the myocardium often suffers damage In addition however some authorities believe that the toxin interferes with neuromuscular control of the peripheral circulation

The mode of action of this exotoxin seems fairly precisely defined It apparently acts as a respiratory enzyme for the parent bacillus When liberated in the tissues of an infected host it acts as a metabolic analog interfering with the host s cytochrome B system

Immunity The chief factor which governs susceptibility to clinical diphtheria is the presence or absence of antibody to the exotoxin This has been demonstrated unequivocally in experimental animals and is also supported by an impressive accumulation of observations on human beings

The *Schick test* is a rough method of determining the amount of antitoxin present in the circulating blood A standard quantity of diphtheria toxin in 0 1 ml fluid is injected intradermally and as a control an equal quantity of toxin previously heated to 70 C is injected into the opposite arm The result is read after 4 to 7 days A positive reaction is indicated by induration and erythema at the site of the toxin injection significantly greater than at the site of the control injection A negative test is indicated by absence of reaction or by reactions of equal intensity at the two test areas A negative Schick test can generally be interpreted as indicating a blood antitoxin level greater than 0 01 unit per milliliter of serum

Antitoxic immunity is not necessarily complete and individuals with a negative Schick test occasionally contract the disease especially if subjected to heavy exposure On the other hand many individuals with a positive Schick test escape diphtheria after being exposed Only about 50 per cent of adults in America are negative to the Schick test yet diphtheria is comparatively uncommon in adult life Furthermore second attacks of diphtheria are very rare despite the fact that only about 90 per cent of patients convalescent from the disease have become Schick negative The implication is therefore that factors other than antitoxic immunity play a part in determining susceptibility to clinical diphtheria There may be resistance to tissue invasion by the organisms themselves In general it may be said that a positive Shick test in a young child is strong evidence of susceptibility whereas in an older person the finding has less significance

Manifestations The incubation period is short usually 1 to 7 days and the early symptoms vary according to the location of the primary lesion

Faucial Diphtheria About half of all cases of diphtheria are of this variety The onset is insidious with slight soreness of the throat malaise and low grade fever gradually increasing in intensity during the next 2 or 3 days The patient usually appears quiet and does not complain excessively of sore throat The body temperature fluctuates between 100 and 102 F The blood pressure is normal and the pulse rate is moderately increased

The characteristic physical findings are in the throat The *diphtheritic membrane* may begin on one tonsil or both It is usually confluent and tends to spread to the adjacent pharyngeal mucosa often upward onto the soft palate and uvula Sometimes it extends across from one faucial area to the other There is little redness elsewhere so that the mucosa only a few millimeters away from the edge of the membrane usually appears normal At first the membrane is filmy or gelatinous but it soon becomes tough and coherent It may be gray yellow or white When an attempt is made to loosen it with an applicator there is bleeding of the underlying tissue When healing begins the membrane separates at the margins rolls up and breaks away in large pieces Therapy with antitoxin usually hastens the separation of the membrane and the return of the mucosa to normal appearance

Nasopharyngeal Diphtheria The membrane may spread from the faucial areas over the posterior pharyngeal wall up into the nasopharynx and even out into the anterior portion of the nose In such

instances the patient is always severely ill and subsequent development of toxic manifestations in the heart or nervous system is to be expected

In severe cases of faucial or nasopharyngeal diphtheria there are marked edema and swelling in the anterior and lateral parts of the neck in addition to enlargement of the regional lymph nodes This is sometimes referred to as "bull neck diphtheria and is generally the severest form of the disease

Anterior Nasal Diphtheria Lesions restricted to this area usually produce mild illness the chief symptom being persistent thin watery sometimes bloody nasal discharge which is irritating and gives the upper lip a raw appearance Toxic manifestations are rare

Laryngeal Diphtheria This may result from extension of nasopharyngeal diphtheria or the lesion may originate in the larynx The first symptom of laryngeal involvement is hoarseness As edema develops in the larynx or as the membrane increases in thickness or extends down into the trachea and bronchi there may be serious encroachment on the air passage Loose edges may flap into the lumen during one of the respiratory phases tending to cause valvelike obstruction Because of the small diameter of the larynx and trachea in young children the danger of respiratory obstruction is greatest in them A croupy stridor dilatation of the nares anxiety restlessness increased pulse rate sweating and flushing of the face are the early signs of obstruction Later there is retraction of the supraclavicular regions lower rib margins and the sternum with each inspiration and cyanosis is evident

Extrarespiratory Diphtheria Primary lesions occasionally develop in other parts of the body They may appear on the vulva or urethra or on wounds burns or chronic ulcers Wound diphtheria is a special problem in tropical areas and is one of the causes of "jungle sores These chronic ulcerated areas do not have a characteristic appearance diagnosis depends on cultural identification of *C diphtheriae* As a rule toxic manifestations especially those of the cardiovascular system are not prominent but peripheral neuritis may occur Healing of such lesions is speeded by administration of antitoxin

Cardiovascular System The frequency of cardiac involvement in diphtheria is illustrated by the fact that abnormal electrocardiograms can be demonstrated in about one half of all patients Various types of disturbance in rate and rhythm are observed The *pulse rate* may be rapid—130 to 170 per minute—or heart block may occur during the second and third weeks with the rate falling to 40 or 50 per minute The effects on the circulation are usually severest during the second week of illness The *blood pressure* tends to be low in some cases hypotension on the order of 70/40 persists for several days This is a grave prognostic sign Patients with severe cardiovascular involvement commonly exhibit marked pallor nausea and vomiting There may be gallop rhythm muffled heart sounds premature ventricular contractions or dropped beats When congestive failure becomes fully developed shortness of breath pain in the region of the liver and distention of the neck veins occur Death is the usual outcome in such cases Occasionally a patient in whom no previous manifestation of cardiac damage has been noted dies suddenly after some slight exertion it is presumed that there has been an acute disturbance in cardiac excitation with either ventricular fibrillation or ventricular standstill

Peripheral Neuritis Evidence of the neurologic complications is seldom observed before the second week of illness and may develop as late as the tenth or twelfth week The commonest initial sign of neural involvement is paralysis of the palate leading to difficulty in swallowing and regurgitation of fluids into the nose There is also a characteristic nasal quality in the voice Second in frequency is involvement of the third cranial nerve giving rise to extraocular paralysis or to impairment of ciliary function and difficulty in accommodation The seventh ninth and tenth cranial nerves may also be affected Less frequent and usually later in time is neuritis of the spinal nerves with paresthesias or weakness of the muscles of the abdomen neck or lower extremities Respiratory paralysis due to involvement of the intercostal and abdominal muscles is rare Loss of the patellar and Achilles tendon reflexes is occasionally seen These neurologic manifestations are not associated with pain but there may be paresthesias especially in the palms and soles Increased spinal fluid protein has been observed in a small proportion of cases of diphtheria and this in combination with postdiphtheritic neuritis may constitute a picture which closely resembles the Guillain Barre syndrome Symptoms of postdiphtheritic neuritis persist from a few days to several weeks usually they improve after the sixth week but instances have been reported in which disability persisted for several months Permanent sequelae however are virtually never encountered

Laboratory Aids Diagnosis by identification of *C diphtheriae* in stained smears from the membranous lesion is unreliable Nonpathogenic diphtheroid bacilli may lead to confusion or true diphtheria bacilli may not be detected A specific diagnosis depends on cultural demonstration of *C diphtheriae* In addition to routine throat cultures

on blood agar material swabbed from the membranous lesion should be inoculated onto Loeffler's and tellurite media Loeffler's medium provides *rapid presumptive diagnosis* organisms with characteristic morphology may be identified in smears from the culture after only 8 to 12 hr incubation For practical purposes this identification if made by a competent bacteriologist and if in conjunction with a compatible clinical picture is adequate Further identification if desired may be made *from the culture on tellurite medium which also* is of assistance in distinguishing the type of *C diphtheriae* Virulence tests need not be done on typical organisms isolated during the acute stage of the disease but they are indicated when the organism is cultured from the throat or nose of an asymptomatic or convalescent carrier

The *leukocyte count* in diphtheria is usually normal but there may be a moderate leukocytosis *Proteinuria* of slight or moderate degree is common during the acute stage and during convalescence Marked proteinuria usually signifies a severe toxemia

Differential Diagnosis The differential diagnosis of lesions resembling faucial diphtheria is discussed in the section on streptococcal infections (p 852) Laryngeal diphtheria must be distinguished from "croup" and laryngotracheobronchitis due to *Hemophilus influenzae* or beta hemolytic streptococcus Croup usually comes on at night improves by morning and is without fever or local membrane In *laryngotracheobronchitis* there are high fever *leukocytosis and diffuse redness and edema of the* air passages usually associated with severe prostration and rapidly progressive respiratory obstruction *Foreign body in the nose* may resemble anterior nasal diphtheria

Complications *Purpura* occurs occasionally in cases with very severe toxemia *Streptococcal infection* is a frequent complication and may cause diffuse redness and edema of the palate and fauces with enlargement and unusual tenderness of the regional lymph nodes (This is one of the reasons why the throat culture should always be made with media suitable for both types of organisms) *Relapse* is extremely rare in diphtheria *Serum sickness* occurs in a variable proportion of patients convales*cent from the disease depending upon the amount* and kind of antitoxin which has been administered

Specific Treatment *Antitoxin* Every patient in whom the diagnosis of diphtheria appears probably should receive antitoxin without delay It is not justifiable to wait until the result of a culture is available The total dose of antitoxin should be given at once a second injection should never be necessary The dose required depends on the severity of the disease not on the age or body weight The severity of the disease is estimated on the basis of the extent of the membrane the amount of edema in the neck the pulse rate the blood pressure and the general appearance of the patient Patients with extensive nasopharyngeal or "bull neck" diphtheria should receive maximal doses In mild cases a dose of 20 000 units is adequate whereas in severe cases considerably larger quantities are needed Many authorities believe that no advantage can be derived from doses of *antitoxin in excess of 100 000 units although it is* the practice in some clinics to give as much as 200 000 units The antitoxin may be injected intramuscularly intravenously or by both routes In severe cases it is a good plan to give half the total dose intravenously and the remainder intramuscularly

Penicillin Therapy Most strains of *C diphtheriae* are sensitive to penicillin in vitro and the drug is employed generally in the treatment of diphtheria Evaluation of its effect has been difficult because of variability in the natural course of the disease and because physicians have been unwilling to withhold antitoxin therapy in order to assay the effectiveness of penicillin alone Certainly penicillin does not neutralize the exotoxin The general experience is however that penicillin therapy has been beneficial in a considerable proportion of the cases and should be used as a routine measure Throat cultures become negative earlier in patients who receive penicillin and the therapy is also of value in preventing or treating pyogenic compli*cations caused by streptococcal infection* A dose of 300 000 units daily for 10 or 12 days should be adequate

Treatment of Laryngeal Obstruction In laryngeal diphtheria death may result from obstruction of the air passages Management of this complication requires experience skill and judgment Patients with laryngeal diphtheria should be observed carefully for signs of obstruction described previously In mild cases some benefit may be afforded by having the patient breathe warm moist air from a steam kettle If obstruction becomes more marked it must be relieved either by intubation or by tracheotomy Intubation is the preferable method in an institution with experienced medical and *nursing staff in the hands of less experienced* personnel tracheotomy is probably the safer measure Where either of these procedures has been done special nurses should be on duty at all times since the tubes may suddenly become obstructed requiring removal cleansing or reinsertion It must be remembered that the patient is unable to call for assistance Tracheotomy or intubation has to *be maintained at least 3 or 4 days and occasionally* a tracheotomy tube is left in place for several weeks

One danger of this is that laryngeal stenosis may occur especially in cases where there has been secondary pyogenic infection around the site of the opening

General Management Isolation precautions should be observed Strict bed rest is indicated and physical effort should be reduced to a minimum during the acute stage as well as during early con valescence from diphtheria Soreness of the throat is usually moderate and swallowing not excessively painful hence local measures such as gargles and irrigations are not advisable as they may facilitate the absorption of toxin

A liquid or soft diet should be prescribed accord ing to the patient s preference Diet high in carbo hydrate and in vitamin C is usually advised but the basis for this has not been very well established If the patient receives an adequate caloric and fluid intake by mouth there is no reason for sup plementing the diet with parenteral feeding

The patient should be observed carefully for evidence of the effect of toxin on the cardiovascular system which is usually at its height during the second week of illness The pulse and blood pres sure should be recorded frequently In patients with hypotension it is common practice to raise the foot of the bed (This is also good procedure in indi viduals with palatal paralysis since it may help to prevent aspiration of material which collects in the throat) Numerous methods have been em ployed in combating heart failure in diphtheria but nothing seems of much benefit Digitalization is not helpful The hypotension can be alleviated by continuous administration of norepinephrine the value of this remains to be determined Intravenous administration of glucose solution is often advocated in treatment of patients with myocardial impair ment but there is no proof that this is beneficial There is no evidence that cortisone therapy reduces the damage caused by the toxin

Six weeks of bed rest is a minimum for patients convalescent from a severe attack of diphtheria In cases where there has been little evidence of toxe mia 2 or 3 weeks in bed is sufficient

Treatment of Carriers *Corynebacterium diph theriae* usually disappears from the throat between the second and fourth weeks but in a small propor tion of patients it may persist longer despite a second course of penicillin In such instances test for virulence of the organism is indicated if nega tive the patient need not be kept under isolation Tonsillectomy is effective in terminating the carrier state in some instances If these measures fail theoretically isolation should be maintained until the throat culture is negative but as a matter of fact experience suggests that after about 6 weeks patients seem to have less tendency to infect others and there is little danger in releasing them

Prophylaxis against Diphtheria Active immuni zation with diphtheria toxoid should be given to every child The first immunization should be carried out at about 6 months of age and the antitoxin response should be checked by a Schick test 6 months later If the child is still positive to the Schick test the course of immunization should be repeated It is advisable to give a booster dose at the time of beginning school, i e at five or six years of age

Active immunization of adults presents a more difficult problem because toxoid often causes severe local and general reactions in them Unless an indi vidual is very likely to be exposed to diphtheria toxoid injections are not indicated after the age of twelve If the decision is made to give toxoid to an adult the so called Moloney test for sensitivity can be employed One tenth milliliter fluid toxoid diluted 1 100 or 1 200 is injected intradermally If this provokes extensive erythema after 12 to 24 hr it is probable that injection of a standard im munizing dose will cause a severe reaction It is advisable then to defer further prophylactic meas ures and repeat the Schick test a few weeks later because these intradermal tests often provide anti genic stimulus sufficient to immunize the individual

Passive immunization is occasionally of value It may be given to the other children in a family or in a hospital ward where a case of diphtheria has developed A dose of 1 500 units of antitoxin can be expected to confer immunity for about 2 weeks

Prognosis The general fatality rate from diph theria varies in different parts of the world from 5 to 12 per cent The prognosis in individual cases is poor if there is extensive membrane with marked edema and lymphadenopathy The usual causes of death are laryngeal obstruction and circulatory failure

Penicillin Therapy Most strains of *C diphtheriae* are sensitive to penicillin in vitro and the drug is employed generally in the treatment of diphtheria Evaluation of its effect has been difficult because of variability in the natural course of the disease and because physicians have been unwilling to withhold antitoxin therapy in order to assay the effectiveness of penicillin alone Certainly penicillin does not neutralize the exotoxin The general experience *is however that penicillin therapy has* been beneficial in a considerable proportion of the cases and should be used as a routine measure Throat cultures become negative earlier in patients who receive penicillin and the therapy is also of value in preventing or treating pyogenic complications caused by streptococcal infection A dose of 300 000 units daily for 10 or 12 days should be adequate

Treatment of Laryngeal Obstruction In laryngeal diphtheria death may result from obstruction of the air passages Management of this complication requires experience skill and judgment Patients with laryngeal diphtheria should be observed carefully for signs of obstruction described previously In mild cases some benefit may be afforded by having the patient breathe warm moist air from a steam kettle If obstruction becomes more marked it must be relieved either by intubation or by tracheotomy Intubation is the preferable method in an institution with experienced medical and nursing staff in the hands of less experienced personnel tracheotomy is probably the safer measure Where either of these procedures has been done special nurses should be on duty at all times since the tubes may suddenly become obstructed requiring removal cleansing or reinsertion It must be remembered that the patient is unable to call for assistance Tracheotomy or intubation has to be maintained at least 3 or 4 days and occasionally a tracheotomy tube is left in place for several weeks

mastication causes trismus and difficulty with chewing This highly characteristic phenomenon gives to the disease its common name of *lockjaw* Sustained contraction of the facial muscles produces a distorted grin called *risus sardonicus* Spasm of the pharyngeal muscles makes swallowing difficult Stiff neck and opisthotonos are also among the early signs Progressively other muscle groups become involved with tightness of the chest and rigidity of the abdominal wall the back and the limbs

The patient is conscious and mentally clear suffering great pain from muscular spasms There is profuse perspiration Fever may or may not be present The wound through which *Cl tetani* was introduced is usually evident although in 10 to 20 per cent of patients it cannot be found Neurologic examination discloses hyperactive tendon reflexes often with sustained clonus There are no sensory changes

The symptoms and signs increase in severity for several days Generalized tonic convulsions appear in all but the milder cases and are accompanied by spasm of the larynx and the respiratory muscles The resulting acute asphyxia may end fatally Convulsions are precipitated by various noxious stimuli such as a sudden noise a hypodermic injection or jostling of the bed If the patient survives the intensity of muscle spasm begins to diminish slowly during the second week Complete recovery may take several months

Occasionally *mild cases* occur in which there is only moderate muscle rigidity without tetanic seizures Sometimes the administration of tetanus antitoxin forestalls the development of generalized tetanus but not of *local tetanus* involving the muscles around the site of injury

Complications are frequent in tetanus Pulmonary atelectasis is common and may be followed by pneumonia which is especially to be dreaded for it seriously lessens the chances of recovery Constipation fecal impaction and urinary retention are often encountered Cystitis and pyelonephritis may develop in patients requiring catheterization Traumatic glossitis is seen frequently Compression fractures of vertebrae may result from the convulsive seizures Decubitus ulcers are likely to occur in patients under heavy sedation Serum sickness may appear 1 to 3 weeks after administration of antitoxin. Foot drop and muscle contractures may follow prolonged unconsciousness with the limbs in poor position Asphyxia from respiratory muscle or laryngeal spasm or from aspiration of secretions vomitus or food may be the immediate cause of death

Laboratory Findings The diagnosis of tetanus must be based on the clinical picture for laboratory examinations are of little assistance It is difficult to isolate the organism from the local lesion, and it is a laborious task to identify it precisely Furthermore the presence of *Cl tetani* in a wound does not necessarily indicate that the patient has tetanus The intoxication itself produces no change in the leukocyte count but leukocytosis may accompany secondary infection The cerebrospinal fluid is often under increased pressure but is otherwise not remarkable The urine is normal unless secondary urinary tract infection is present

Differential Diagnosis The incipient stages may resemble certain other conditions but fully developed tetanus is likely to be confused with few other diseases A frequent diagnostic problem is differentiation of *serum sickness* from early tetanus Many patients with injuries are given tetanus antitoxin and some subsequently develop serum sickness with temporomandibular arthralgia and trismus Usually arthralgia of other joints is also present together with urticaria and generalized adenitis Other conditions in which trismus occurs include *peritonsillar* abscess and local infections of the mouth and cervical region The finding of a normal spinal fluid in tetanus eliminates confusion with *meningitis* The clinical picture of *strychnine poisoning* with hyperexcitability of the muscles opisthotonos "risus sardonicus" and tonic convulsions may closely mimic tetanus except that the muscles are relaxed between seizures in strychnine intoxication while spasm tends to persist in tetanus In *rabies* inability to swallow is often an early symptom with drooling of saliva and spasms of the muscles of deglutition, followed by fever anxiety excitement delirium hyperesthesia, and convulsions A history of animal bite usually is obtainable

Treatment This is a grave disease for which unfortunately there is no specific treatment Nevertheless careful and constant attention to certain supportive measures often will change the outcome from death to recovery

Sedation A most important feature in therapy is the continuous use of sedatives in quantities sufficient to induce partial relaxation of muscle spasm and to prevent the dangerous acute tetanic seizure To accomplish this it sometimes becomes necessary to induce a state of unconsciousness yet one must avoid depression of respiration Various drugs have been used including barbiturates paraldehyde magnesium sulfate and tribromoethanol It is preferable to employ a combination of two drugs for example Sodium Amytal and tribromoethanol in an effort to minimize the toxic effects of each Sodium Amytal can be given orally subcutaneously or in an emergency intravenously in a dose of 0 25 to 0 5 Gm Tribromoethanol is administered *per rectum* in a dose of 15 to 30 mg per kg body weight Precise dosage schedules must be determined em

138 TETANUS

Edward S Miller

Definition Tetanus is a severe intoxication characterized by generalized hypertonicity of skeletal muscles and convulsive seizures The manifestations result from the action of an exotoxin produced by *Clostridium tetani*

History Tetanus was described by Hippocrates and has been known since ancient times as a scourge of parturient women newborn babies and wounded soldiers As recently as the eighteenth century one out of every six infants born in the Rotunda Hospital in Dublin died of tetanus neonatorum The record was no more enviable in other parts of the world Studies beginning in 1884 demonstrated that the disease is caused by a toxin producing *Clostridium* In succeeding years immunologic methods were developed for the prevention of the disease

Etiologic Agent *Clostridium tetani* is a large motile spore forming gram positive bacillus without a capsule It is an obligate anaerobe and can be cultivated on artificial media in the absence of atmospheric oxygen Characteristic spherical terminal spores are produced which are highly resistant if protected from direct sunlight they can survive for many years Tetanus spores are often present in the intestinal contents of man and animals and have been found in soil and street dust in many parts of the world Under suitable conditions of growth *Cl tetani* elaborates a powerful exotoxin At least 10 antigenic types of the organism have been distinguished but differentiation is of no practical importance since the exotoxins of all have the same immunologic properties

The vegetative forms of *Cl tetani* and the exotoxin are destroyed by heating to 65 C for 10 min Spores can be killed by autoclaving it a temperature of 115 C for 20 min

Pathogenesis and Epidemiology The etiologic agent is carried into human tissues by contamination of a wound A variety of lesions both large and small may offer a suitable haven for growth lacerations compound fractures gunshot wounds burns frostbites bedsores and penetrating lesions produced by nails human and animal bites and slivers Cases have resulted from the use of unsterile surgical supplies and biologic materials Infections of the post partum uterus and the umbilical stump (tetanus neonatorum) were once extremely common but became rare after the introduction of aseptic obstetric techniques *Clostridium tetani* is so ubiquitous in the human environment that almost any contaminated wound may contain the organisms

The mere fact that *Cl tetani* is present does not necessarily mean that tetanus will develop local conditions in the wound must be suitable The organisms will proliferate only in the presence of an oxidation reduction potential far lower than that existing in normal living tissue Such a fall in potential may occur as a result of the presence in the wound of necrotic tissue soil cloth metal wood or of tetanus toxin Once the organism begins to grow it produces toxin and thereafter can itself maintain the conditions necessary for continued multiplication If the conditions for growth are not optimal tetanus spores may persist in the tissues for many months in a dormant but viable state Some may be carried by phagocytes to distant parts of the body If such tissues are later traumatized (as by surgical procedure) tetanus may then develop

Tetanus bacilli grow locally in a wound show little capacity to invade and are in themselves harmless They cause disease by virtue of a soluble exotoxin elaborated in the course of growth Actually two toxins are produced tetanolysin and tetanospasmin Tetanolysin has a lytic effect on red corpuscles in vitro and may also be damaging to leukocytes Its exact clinical effect is unknown but *it may contribute to tetanus infection by causing* local tissue necrosis and by antiphagocytic action Tetanospasmin is a protein substance with potent neurotoxic properties It is estimated that a dose of 0 13 mg is lethal for man The toxin acts at two points in the body on the neuromuscular end organs causing sustained muscle spasm and on the motor nerve cells of the spinal cord medulla and pons causing convulsive seizures Tetanospasmin has a strong affinity for nerve tissue of susceptible animals and when once combined with it in vivo cannot be neutralized by any amount of antitoxin The means by which toxin travels from the local lesion to the nervous system is still a matter of controversy According to one theory the toxin enters the neuromuscular end organs passes centripetally up the axones of motor nerves to the cord then spreads throughout the nervous system However other evidence makes it seem more likely that the toxin is carried to the nervous system via the circulating blood

Manifestations The incubation period varies from 2 days to several months but in two thirds of cases it falls within the range of 6 to 15 days Some patients have prodromal symptoms of restlessness and headache In others the first symptoms are those stemming from the developing muscular rigidity with vague discomfort in the jaws neck or lumbar region Among the first muscles to show involvement are those innervated by the cranial nerves particularly the fifth seventh ninth tenth eleventh and twelfth Spasm of the muscles of

in which antitoxin was given generalized allergic reactions occurred in 9 per cent of patients who had not had previous serum injections and in 24 per cent of those who had Furthermore patients who have had previous experience with horse serum often exhibit great acceleration in the rate of removal of antibody from the blood so that passive protection in them is short lived Another limitation to the use of antitoxin is the fact that not all who need it receive it In one-third to one half of cases of tetanus illness follows a wound so trivial that it is disregarded by the patient or is considered by the physician to be too insignificant to warrant antitoxin prophylaxis

Active immunization provides the most satisfactory type of prophylaxis A toxoid is used and initial immunization is achieved by giving two doses of an alum precipitated preparation or three doses of fluid toxoid at monthly intervals A booster dose is administered after 1 year and thereafter at intervals of 4 years A booster dose of fluid toxoid is likewise given immediately after an injury The antibody response to basic immunization is slow so that if active immunization is initiated at the time of injury the patient will not get the protection he needs However if he has previously received toxoid a satisfactory rise in serum antibody titer will occur within 4 to 6 days Ordinarily a booster dose after an injury may be relied on as late as 10 years after the last previous toxoid injection However there are occasional situations involving actively immunized individuals in which conservative judgment indicates the simultaneous administration of both antitoxin and toxoid (utilizing opposite arms) This should be done in massively contaminated large or multiple wounds particularly if they involve the head or neck It should also be done if there is doubt regarding previous active immunization or if there is delay in administering the booster

The foregoing discussion supports the proposition that all people should receive the benefit of routine active immunization Not only will this provide protection against tetanus but of even greater practical importance is the fact that it will obviate the frequent necessity of administering antitoxin with all the attendant hazards of sensitization A large pool of actively immunized individuals already exists in the United States including those who served in the armed forces and the many children who have benefited from pediatric immunization programs during the past 20 years Their immunity should not be permitted to wane It is particularly urgent that toxoid be administered to all patients who have allergies and to all who have received injections of horse serum In the latter group active immunization should be initiated 2 weeks after serum is given

Prognosis Case fatality rates are in the range of 30 to 40 per cent The outlook is especially grave in young children in the aged and in patients who develop pneumonia or other secondary infections It is worse if the incubation period is less than 7 days and if tetanal spasms supervene within 2 days after onset of other clinical signs Most deaths occur within the first 10 days of illness Survivors make a complete recovery Interestingly they are not immune to reinfection

139 BOTULISM

Edward S Miller

Definition Botulism is an intoxication resulting from absorption of a poisonous substance produced by *Clostridium botulinum* The illness is characterized by generalized muscular weakness and frequently ends in death

History This disease was first described in Europe over 200 years ago It was sometimes seen in individuals who had eaten contaminated sausages For this reason the name of the illness is derived from the Latin word for sausage Outbreaks of botulism have been observed in the United States for many years chiefly in association with the consumption of inadequately processed canned foods

Etiology *Clostridium botulinum* is a motile gram positive bacillus which produces subterminal spores It grows readily on artificial media but only under anaerobic conditions The organisms are natural inhabitants of the soil and are found in abundance in many parts of the world In the United States the soils of the Rocky Mountain and the Pacific Coast regions are most heavily infested Organisms are frequently present on fruits and vegetables and thus are carried into the gastrointestinal tracts of animals and of man

pirically as indicated by the patient s condition It is often possible to reduce the amount of sedation required by gentle nursing care use of tracheotomy and administration of muscle relaxants as indicated below

Antiserum As soon as the patient has received adequate sedation he is given 100 000 units of antitoxin intramuscularly Hyaluronidase may be mixed with the serum to hasten absorption Serum never should be given intraspinally Prior to any surgical procedure 10 000 units may be infiltrated around the local lesion The usual tests for horse serum sensitivity must be performed beforehand This dose is sufficiently large to provide a safe excess of circulating antitoxin for 7 weeks or longer Repeated doses are not necessary except in unusual cases *involving extensive slow healing wounds* where readministration may have to be considered Antitoxin has no curative action in tetanus for it has no effect on the toxin which is already combined with nerve tissue Its only action is to neutralize newly formed toxin as it is produced in the lesion and before it has reached susceptible nerve cells

Treatment of Local Lesion The patient should receive sedatives and antiserum before the site of infection is manipulated The local lesion is then treated according to the same surgical principles that would be applicable if tetanus were not present Specifically a limb should not be amputated simply because the patient has tetanus

Nursing Care There is no disease in which meticulous gentle nursing care is of greater importance Constant attendance by special nurses is essential The patient should be in a quiet darkened room where all external stimuli such as noise drafts and jarring are kept to a minimum Secretions which accumulate in the pharynx must be removed by suction and postural drainage It has been shown that a 25 elevation of the foot of the bed is necessary to achieve successful postural drainage A padded tongue depressor should be placed between the teeth to prevent biting of the tongue during convulsions Bedsores can be avoided by use of a foam rubber mattress by changing the patient s position frequently and by special attention to care of the skin An indwelling catheter may be necessary because of persistent urinary retention Enemas should be given as needed to overcome constipation and prevent fecal impaction Foot drop and wrist drop can be prevented by suitable positioning with pillows sandbags or splints

Feeding Oral feeding usually is impossible because of trismus Intravenous feeding must be used during the most severe phase of illness and particularly in heavily sedated or unconscious patients It is best not to give fluids subcutaneously because the attendant pain stimulates the patient unduly In mild cases and in those who are recovering gavage is permissible utilizing a nasogastric tube of small caliber

Tracheotomy This simple surgical procedure has proved to be a safe and extremely valuable therapeutic adjunct in selected cases The successful application of tracheotomy in bulbar poliomyelitis has pointed the way to its wider use in other diseases such as tetanus in which airway obstruction often leads to anoxia pulmonary edema atelectasis and pneumonia The trachea can be suctioned easily and bronchoscopy can be employed when necessary Specific indications include spasm of the respiratory muscles laryngeal obstruction absent cough and swallowing reflexes excessive pharyngeal and tracheal secretions and coma In other words tracheotomy may be used to advantage in most moderately to severely ill patients Following tracheotomy it is often found that convulsive seizures are fewer and fewer sedatives are needed

Chemotherapy Penicillin is administered because of its curative effect on the tetanal infection itself

Muscle Relaxants Various agents of this type have been employed with varying degrees of success Curare is considered by many clinicians to be too dangerous because of the narrow margin between a relaxing dose and one which produces respiratory paralysis A depot form such as *d* tubocurarine in oil is somewhat less hazardous and longer lasting than the aqueous solution but should be used only when means of providing artificial respiration are at hand Mephenesin is somewhat less effective but is safer and therefore is perhaps a more satisfactory agent It can be administered intravenously as a 2 per cent solution in doses of 25 to 300 ml

Prophylaxis In the prevention of tetanus it is important that contaminated wounds receive thorough and prompt debridement Penicillin should be given because it has a definite effect in preventing or curing tetanal infection although it has no antitoxic properties In addition either active or *passive immunization is used to raise the resistance* of the patient

Immediate passive protection is achieved by administering horse serum antitoxin parenterally in a dose of 1 500 to 10 000 units depending on the extent of the lesion and the lapse of time between injury and treatment It acts by neutralizing free toxin and has no bactericidal effect Its use has been attended by great success only rarely does tetanus follow serum prophylaxis However there are serious disadvantages to its use It provides protection for only a week or two A significant proportion of patients exhibit allergic reactions including localized hypersensitivity serum sickness and rare but catastrophic anaphylactic shock In one large series

there may be hypersecretion of the lacrimal salivary and sweat glands but this is soon followed by diminished function Early in the illness excessive vagal tone sometimes causes the pulse rate to drop below 50 per minute Subsequently there are vagal depression and tachycardia Hypotension may occur as a result of peripheral vascular dilatation

The most significant physical alterations are seen in the nervous system Nearly all patients exhibit cranial nerve palsies involving any except the olfactory and optic nerves Weakness of the intrinsic and extrinsic eye muscles results in loss of the light and accommodation reflexes mydriasis ptosis strabismus diplopia or nystagmus The face becomes expressionless because of the seventh nerve paralysis Chewing swallowing and phonation are interfered with and the tongue cannot be controlled The neck muscles are unable to support the head The limbs become progressively weaker and movements may be incoordinated Complete paralysis of a limb is rarely encountered since death supervenes before this occurs Pulmonary ventilation is diminished as a result of weakness of the intercostal muscles and the diaphragm and cyanosis appears The superficial and deep reflexes are diminished but rarely absent The sensory system is intact

The paralysis may progress to a fatal termination after 2 to 10 days of illness Death results from paralysis of the respiratory muscles from obstruction of the airway or from attendant pulmonary infection In nonfatal cases the muscular weakness increases over a period of 10 days then almost imperceptibly function begins to return The muscles involved in respiration deglutition and speech are the first to show improvement Visual abnormalities persist for weeks or months Two to six months elapse before all symptoms disappear

Laboratory Findings The clinical diagnosis can be substantiated by identifying botulinus toxin either in the food or in the body of the patient A suspected specimen is suspended in saline solution and inoculated into mice If toxin is present the animals become paralyzed whereas control mice passively immunized with specific antiserum are protected The toxin can occasionally be demonstrated in the stomach or intestinal contents in the peripheral blood during life or in organ extracts after death Additional evidence may be gained by culturing *Cl botulinum* from the food although it must not be forgotten that the organism may be a harmless contaminant

The disease produces no characteristic changes in the leukocyte or erythrocyte counts in the urine or in the spinal fluid The electrocardiogram may show flattening of T waves and depression of S T segments

Differential Diagnosis Botulism may be confused with other diseases of toxic or infectious origin One should seek a history of recent consumption of home preserved foods and of coincident illness among other human beings or animals that shared the food Cranial nerve palsies and other paralytic phenomena are seen at times in poliomyelitis in viral encephalitis and in acute infectious polyneuritis These diseases are often accompanied by fever and by spinal fluid abnormalities In postdiphtheritic paralysis a history of preceding sore throat usually can be obtained The paralysis of shellfish poisoning appears a few minutes after ingestion of the sea food and is accompanied by paresthesia giddiness and somnolence In mushroom poisoning there are severe pains with marked vomiting and diarrhea Intoxication with the belladonna group of alkaloids leads to fever tachycardia and delirium An overdose of curare results in the rapid onset of widespread paralysis with death or recovery in the course of minutes or a few hours Myasthenia gravis is usually easily differentiated

Treatment and Prophylaxis Botulism is most satisfactorily controlled by prevention for methods of treatment are inadequate Practically all human cases are due to either type A or type B toxin and a bivalent antitoxin is available for prophylaxis and for therapy When the diagnosis is suspected on clinical grounds the antitoxin should be administered immediately by the intravenous route in a total dose of 100 000 units The antiserum will not reverse the effects of toxin which has already damaged the myoneural junction but it will neutralize that which has not yet been fixed by the receptor cells Early administration therefore is important The same dose should be given prophylactically to other individuals who have eaten the contaminated food but have not yet developed symptoms

The patient should be kept at strict bed rest There may be residual toxin in the gastrointestinal tract therefore it should be emptied by gastric lavage by enema and by catharsis Hypotension and shock can be counteracted by appropriate measures Careful and continuous nursing care is essential

Respiratory failure and airway obstruction are fundamental features which lead to death and every effort must be made to overcome these dangers The problems are similar to those encountered in poliomyelitis with respiratory paralysis Many of the newer therapeutic techniques which have proved successful in that disease are applicable to the treatment of botulism (see p 1076) When the swallowing reflex is lost oral feeding becomes dangerous and must be replaced by nasogastric tube or intravenous feeding Pharyngeal secretions are removed by suction and by postural drainage The patient should be placed in a mechanical respirator with the first signs of weakness of the

This organism produces an extremely potent exotoxin (called *botulin*) *under suitable conditions* of anaerobic growth in a variety of foodstuffs of animal and plant origin There are five different immunologic varieties of *Cl botulinum* designated as types A B C D and E They differ in that each produces a specific exotoxin which is antigenically distinct from the others These toxins are by far the most potent poisons known Type A toxin has been isolated in pure crystalline form and identified as a globulin with a molecular weight of approximately 1 000 000 Type B toxin has likewise been purified and found to possess a molecular weight of 60 000 There are no qualitative differences in the effects of the different types of toxins but there are marked species differences in host susceptibility Human cases are usually due to types A and B and rarely to E only one case of type C has been reported and none of type D

Some spores can withstand boiling for as long as 22 hr but are killed by moist heat at 120 C in 4 to 20 min The exotoxin is more labile and is inactivated by boiling for 10 min

Pathogenesis Botulism occurs as a result of the ingestion of toxin which has previously been formed in food The botulinus bacillus does not produce toxin in the alimentary tract and therefore is harmless when ingested This organism frequently contaminates foodstuffs but no human disease has resulted from the consumption of fresh food However the spores will survive and produce toxin if improper methods of food preservation are employed The products implicated are canned fruits and vegetables and canned or preserved fish and meats as well as cheeses Commercial packers in *this country now use sterilizing techniques which* are adequate to destroy all spores The chief danger lies in home canned products particularly when high pressure steam methods are not utilized Because of this most outbreaks in the United States have occurred in individual families or other small groups About fifteen such outbreaks are reported annually in this country the majority of them in California Washington and Colorado

Spoilage of food may be suspected because of abnormal taste odor gas turbidity or softening but there may be no observable alterations Therefore when possible home preserved products *should be boiled for 10 min before use* Needless to say any item which appears to be spoiled must be destroyed without being tasted Care must be taken to prevent contact of contaminated food with cuts on the hands for a dangerous quantity of botulin might conceivably be absorbed

The natural and usual portal of entry of botulin is via the gastrointestinal tract The toxin is a protein yet it resists digestion It is absorbed intact from the small *intestine* and possibly also from the stomach but poorly from the colon Until recently *it was believed that this represented the only nat*ural means by which human beings acquire botulism though it has long been known experimentally that animals are far more susceptible to botulin *administered parenterally than to that re*ceived via the oral route It is therefore of interest to note several recent reports which indicate that *Cl botulinum* can sometimes proliferate in contaminated wounds produce toxin and thus cause clinical botulism in man This is an entirely new concept of pathogenesis and demands a careful evaluation of the course of illness in patients with wound infections particularly in the presence of gas gangrene

Botulinus toxin exerts a highly specialized biochemical effect acting only on nerve cells The principal and probably the only sites of action are at the myoneural junctions and at parasympathetic nerve endings It has no effect on the central nervous system it does not abolish conduction in the nerve itself it does not affect the reactivity of the end plate *nor is there any firm evidence of effect* on muscle The toxic effect pertains to acetylcholine either in inhibiting its synthesis or in preventing its release from the terminal fibers

Botulism is not limited to man The natural disease occurs in a varied assortment of wild and domesticated animals and birds while still others are susceptible to experimental inoculation The disease is sometimes seen in chickens or cats in relation to human outbreaks when these animals are fed scraps from the table

Manifestations Following ingestion of botulin there is a latent period usually in the range of *12 to 36 hr though it may be as short as 2 hr or as* long as 14 days The incubation period is shortened and the severity of illness increased as the size of the dose is increased

Illness begins insidiously with fatigue weakness headache and dizziness Digestive complaints are observed in only one third of cases and probably are due to local irritation from other substances in the spoiled food rather than to the toxin They consist of nausea vomiting upper abdominal discomfort and diarrhea Such symptoms subside after a few hours and thereafter there is obstipation with abdominal distention but without tenderness *or pain Botulism is essentially a generalized para*lytic disease and these manifestations soon dominate the clinical picture Weakness is noted during the first 24 hr in the muscles innervated by the cranial nerves Soon it spreads to the rest of the skeletal system Except for headache botulism does not give rise to pain

The patient is clear mentally and remains so throughout the course of his illness There is no fever unless secondary infection occurs Initially

injected into undamaged tissues of experimental animals The nature and the amounts of toxin produced vary considerably for different species and strains *Clostridium welchii* elaborates alpha toxin a lecithinase which is the principal tissue-destroying hemolytic and "lethal" toxin Other *Cl welchii* toxins include collagenase hyaluronidase hemolytic theta toxin a substance that damages vascular endothelium and a factor that inhibits leukocyte migration and phagocytosis None of these organisms produces a neurotoxin muscle spasm or paralysis in a patient with gas gangrene indicates concurrent tetanus or botulism

Gas Gangrene (Clostridial Myonecrosis)

Gas gangrene occurs as a complication of extensive injury to skeletal muscle The incubation period is usually 1 to 4 days but may vary from 6 hr to 6 weeks or longer The earliest symptom is sudden severe pain in the injured part The distal portion of an involved limb becomes cold and edematous within a few hours and eventually pulseless and gangrenous The wound drains a watery brown material with a characteristic sweet foul odor The surrounding skin is usually dusky brown or reddish and vesicles or hemorrhagic bullae may develop particularly in *Cl septicum* infections Gas is usually not detectable in the tissues by palpation but tiny bubbles may be seen in the discharge from the wound The involved muscle appears dark red or black herniates through the wound and sloughs at the surface

Systemic manifestations developing shortly after onset of severe pain and swelling of an injured extremity strongly suggest gas gangrene The patient is prostrated pale and motionless but is usually well oriented alert and extremely apprehensive The temperature usually does not exceed 101 F and may be normal As the illness progresses there may be anorexia vomiting profuse watery or bloody diarrhea and eventually circulatory collapse with clammy skin tachycardia hypotension and sometimes wide pulse pressure and dicrotic pulse Intravascular hemolysis is rare with *Cl welchii* myositis Pericardial effusion is sometimes noted Delirium and coma may precede death but more commonly the patient dies suddenly several days after onset often during surgery or anesthesia or while only being moved Acute renal failure is occasionally a late complication

Gas gangrene must be differentiated from nonclostridial infections of gangrenous limbs caused by anaerobic streptococci (p 869) or aerobic gas forming coliform bacilli (p 879)

Clostridial Cellulitis

This is a relatively benign infection of the skin and subcutaneous tissues that occurs in approximately 5 per cent of wounds contaminated with pathogenic clostridia The disease is characterized by spreading necrosis of superficial tissues and a profuse foul smelling brown seropurulent exudate Gas which crepitates on palpation invariably forms in the subcutaneous tissues and may involve an entire limb or form a localized gas abscess In clostridial cellulitis the underlying skeletal muscle is not involved pain is not severe and the only systemic manifestations are slight fever and moderate tachycardia It can usually be differentiated from streptococcal cellulitis by the presence of subcutaneous gas and the absence of erythema

Postabortal and Puerperal Sepsis

Uterine infections with *Cl welchii* usually occur after incomplete abortions induced under unsterile conditions and rarely after spontaneous abortions or prolonged labor at term The organisms presumably invade the damaged endometrium through the retained products of conception The earliest symptoms are caused by instrumentation and consist of metrorrhagia suprapubic and back pain chills and fever Fever of 100 to 103 F often with chills usually recurs several days after abortion but the incubation period can be as short as 6 hr Vaginal bleeding is almost invariably present and there is often a brown foul smelling vaginal discharge containing necrotic tissue The cervix is soft and patulous and the uterus and adnexae are usually very tender The lower abdominal wall is often tense or signs of generalized peritonitis may be present secondary to perforation of the uterus or parametrial extension of infection Nausea vomiting and profuse diarrhea are often prominent Unusual local complications of the uterine infection are gas gangrene of the vagina and rectum with formation of a cloaca and clostridial cellulitis of the anterior abdominal wall following cesarian section or hysterectomy At times the infectious process is confined to the endometrium and myometrium with intrauterine gas formation (physometra)

Systemic manifestations usually appear with dramatic suddenness As in gas gangrene the clinical picture is dominated by circulatory collapse with hypotension extreme tachycardia cyanosis hyperpnea and pulmonary edema Despite severe prostration the patient is well oriented alert and apprehensive almost to the end Massive intravascular hemolysis accompanied by hemoglobinemia hemoglobinuria and jaundice is often the most striking feature of the disease Death may occur a few hours after onset or be delayed for several days Patients who recover from the acute episode of shock dehydration and hemolysis frequently develop acute renal failure

Diseases to be considered in the *differential diagnosis* include perforated uterus ruptured ectopic

respiratory muscles Tracheotomy is an essential part of the program providing an unobstructed air way and a means of removing tracheal secretions

Narcotics sedatives and other respiratory depressants are strictly contraindicated even though patients are often apprehensive and restless

Effective toxoids have been developed for protection against both types A and B toxins They are useful chiefly in protecting laboratory workers

Prognosis The fatality rate in type A cases is 70 per cent while in type B cases it is 20 per cent or less If a patient survives the first 10 days of illness his chances of recovery are good Convalescence may take as long as 6 months but it leads eventually to complete restoration of function

140 OTHER CLOSTRIDIAL INFECTIONS

Edward W Hook and Robert R Wagner

Introduction and History Bacteria of the genus *Clostridium* are normal inhabitants of soil and the gastrointestinal tract of man and animals Most of the 50 species that have been recognized are saprophytic but others are infectious for man and animals usually under conditions of lowered host and tissue resistance Infections with these organisms are often associated with profound systemic manifestations and all pathogenic clostridia except *Clostridium tetani* (p 924) and *Cl botulinum* (p 927) are capable of causing extensive tissue destruction at the site of invasion Diseases caused by these other clostridia include gas gangrene cellulitis postabortal and puerperal sepsis and rarely pleurisy peritonitis or meningitis In addition ingestion of food contaminated with certain clostridia may cause enterocolitis without the neurologic manifestations of botulism

Hippocrates and Celsus were aware of the relationship between penetrating wounds and gas gangrene but the nature of this disorder was not appreciated until the discovery of pathogenic clostridia by Pasteur Novy and Welch The incidence of gas gangrene diminished markedly with the advent of antiseptic surgery in the latter half of the nineteenth century only to rise again to epidemic proportions during the trench warfare of the First World War The rarity of serious clostridial infections in United Nations troops in Korea attests to the advances in surgical management of war wounds Gas gangrene and clostridial cellulitis are still encountered in neglected civilian injuries and clostridial infections of the uterus account for a large proportion of deaths from criminal abortions

Etiology Wounds complicated by gas gangrene usually contain a mixture of pathogenic and saprophytic clostridia often including *Cl tetani* as well as a variety of other organisms *Clostridium welchii (perfringens) Cl oedematiens (novyi)* or *Cl septicum* (vibrion septique) can be cultured from most cases of gas gangrene and clostridial cellulitis and *Cl welchii* causes virtually all clostridial infections of the uterus *Clostridium bifermentans Cl sporogenes Cl histolyticum* and *Cl fallax* are less virulent organisms that occasionally cause gas gangrene but are more commonly associated with localized cellulitis *Clostridium botulinum* has also been isolated from wound infections of several patients with clinical manifestations of botulism (see p 928)

The clostridia of gas gangrene and related infections are anaerobic or microaerophilic gram positive bacilli that produce abundant gas in artificial media and form subterminal endospores *Clostridium welchii* is encapsulated and nonmotile rarely sporulates in artificial media and its spores can be destroyed by boiling

Epidemiology and Pathogenesis Clostridia do not penetrate intact skin or mucous membranes but gain entrance to the tissues through penetrating wounds or perforated abdominal viscera Gas gangrene develops only in devitalized tissues in which the arterial circulation has been compromised by trauma constricting tourniquets or casts or by obliterative arterial disease Infection is most frequent after severe muscle injuries particularly of the thigh and is more common in wounds complicated by compound fractures or lodgment of foreign bodies

Gas gangrene and related infections are characterized by extensive necrotizing myositis edema thrombosis of small vessels interstitial gas bubbles and minimal infiltration of leukocytes Although bacteremia may occur infection at distant sites is rare Clostridia produce potent exotoxins during the course of infection spores or vegetative forms washed free of toxin are completely innocuous when

Section 8 Mycobacterial Infections

141 TUBERCULOSIS

William M M Kirby

Definition Tuberculosis is an infectious disease of protean manifestations which is widespread among man and animals The initial lesion is usually located in the lung and from it tubercle bacilli may spread by intrabronchial dissemination or by direct extension or they may be carried in the blood stream to many organs throughout the body causing destructive lesions at the time of dissemination or after long periods of latency In the majority of individuals the primary infection becomes arrested but it causes alterations in the immunologic state of the host which modify the response of the tissues to subsequent reinfection or to exacerbation of the primary infection Pathologically varying degrees of exudation production tubercle formation necrosis and fibrosis are observed depending on the organ involved the number of infecting bacilli the virulence of the organisms and the immunologic state of the patient

History The discovery of lesions involving the bones of a Neolithic man and of Egyptian mummies indicates that man has been afflicted with tuberculosis during much of his evolutionary development The contagiousness of tuberculosis was recognized by Aristotle and the name *phthisis* was conferred by Hippocrates because of the marked bodily wasting produced by the disease An important advance occurred in 1819 when Laennec asserted in his treatise on the use of the stethoscope that tubercles wherever present were manifestations of a single disease process This disputed doctrine was supported by the inoculation experiments of Villemin in 1865 and was finally proved by the discovery of the tubercle bacillus by Koch in 1882 Subdivision of the tubercle bacilli pathogenic for man into three types followed the avian bacillus being isolated by Maguccı in 1890 and human and bovine types being differentiated by Theobald Smith in 1898

A most important development in the history of tuberculosis was the discovery of streptomycin by Waksman and his associates in 1944 The early studies of Hinshaw and Feldman indicated that streptomycin possessed therapeutic potentialities unapproached by earlier chemotherapeutic agents Lehmann working with derivatives of benzoic acid was responsible in 1943 for experiments leading to the synthesis and eventual clinical utilization of para aminosalicylic acid Isoniazid was discovered independently in 1951 by three groups of chemists who were studying the tuberculostatic action of derivatives of nicotinic acid

Prevalence and Incidence Tuberculin surveys and autopsy studies 50 years ago indicated that virtually 100 per cent of the population was infected prior to the age of twenty The situation has changed greatly since that time in the United States for example tuberculin surveys now reveal only 20 per cent of positive reactors in young adults and it is estimated that less than 50 per cent of the total population is infected Skin hypersensitivity is known to disappear in a certain percentage of individuals and consequently autopsy studies yield higher figures than tuberculin surveys Autopsies performed by Medlar in New York City from 1944 to 1946 showed that the incidence of infection in individuals over fifty years of age was above 80 per cent These studies indicate that the decline in the incidence of infection has occurred chiefly among the younger age groups

The *morbidity*—i e the frequency of actual tuberculous disease—is difficult to estimate accurately but most authorities agreed that there were approximately 350 000 active cases in the United States in 1957 Thus although almost half the total population was infected by the tubercle bacillus clinically significant disease develops in only a relatively small number of individuals

There has been a striking decline in the *mortality rate* from tuberculosis during the past 50 years From first place in 1900 with over 200 deaths per 100 000 population tuberculosis by 1940 had fallen to seventh place as a leading cause of death with a mortality rate of 45 9 per 100 000 By 1950 the figure had fallen to only 22 and in 1954 it was 10 The most important factors in this decline have been the improvement in living standards with better nutrition and housing shorter working hours and earlier diagnosis and treatment Tuberculosis remains one of the major causes of death in young adults ranking fourth in the age group fifteen to thirty four

Since 1945 the mortality rate has declined more precipitously than during the preceding two decades because of the advent of chemotherapy From 1938 through 1945 the death rate declined about 3 per cent each year From 1946 through 1951 the average annual decline increased to 11 per cent and in 1952 (when isoniazid was introduced) through 1954 it was 20 per cent

Unfortunately there has not been a proportionate decrease in the number of newly discovered active infections Since 1930 for example the

pregnancy ingestion of toxic abortifacients streptococcal or staphylococcal puerperal sepsis pelvic thrombophlebitis with septic pulmonary emboli acute hepatic necrosis of pregnancy sickle cell crisis and Weil s disease

Clostridial Infections of Serous Surfaces

Pathogenic clostridia are occasionally introduced into the abdomen thoracic cavity or cranium through penetrating wounds or surgical incisions Actual visceral infections with these organisms are exceedingly rare and almost invariably associated with a mixed bacterial flora Clostridial pleurisy may involve the underlying lung but is usually an *indolent localized infection with minimal systemic* manifestations Clostridial meningitis is often associated with a necrotizing cerebritis Clostridial peritonitis may follow perforation of the gallbladder appendix or other viscus and is usually rapidly fatal Necrotizing hepatitis caused by *Cl oedematiens* has been described

Clostridium welchii Food Poisoning

Meat and meat products contaminated with *Cl welchii* have been responsible for outbreaks of acute gastroenteritis Nausea vomiting abdominal cramps and diarrhea occur 8 to 12 hr after ingestion of the incriminated food and persist for 12 hr or less Systemic manifestations are usually absent and recovery is uneventful in most outbreaks although a severe form of the disease in Germany known as enteritis necrotans has been *associated with a high incidence of intestinal ob*struction severe dehydration shock and death The intestinal flora is not significantly altered and attempts to demonstrate specific toxins by feeding clostridial cultures to human volunteers have not been uniformly successful

Laboratory Findings The diagnosis of gas gangrene clostridial cellulitis postabortal sepsis or other clostridial infections is based primarily on clinical criteria Smears of wound exudate or uterine scrapings may show abundant gram positive *bacteria as well as other organisms Thioglycollate* broth deep meat broth and blood agar plates incubated in an anaerobic jar should be inoculated for definitive identification of specific clostridia However *interpretation of positive wound cultures is* difficult because clostridia are frequent contaminants *Clostridium welchii* septicemia and bacilluria are common in postabortal infections but rare in gas gangrene and other clostridial infections All attempts to demonstrate circulating toxins have been unsuccessful

Polymorphonuclear leukocytosis occurs frequently in gas gangrene and invariably in post abortal sepsis total blood leukocyte counts occasionally *exceed 60 000 cells per cubic millimeter* Marked thrombocytopenia has been described in clostridial sepsis X ray examination sometimes reveals the presence of gas in the muscles subcutaneous tissues or uterus The urine frequently contains protein and casts Renal insufficiency may lead to severe and irreversible azotemia hyperpotassemia hyperphosphatemia and acidosis

Profound alterations of circulating erythrocytes are common in postabortal sepsis but rare in other clostridial infections Hemolysis results in severe *anemia hemoglobinemia hemoglobinuria and ele*vated levels of indirect serum bilirubin Spherocytosis increased osmotic and mechanical fragility of the red blood cells erythrophagocytosis and methemoglobinemia have also been described

Treatment Serious clostridial infections require prompt surgical intervention Early debridement or amputation of the involved extremity may afford dramatic relief of the systemic manifestations of gas gangrene Curettage of the uterus should be performed for diagnosis and treatment of post *abortal clostridial infections Hysterectomy probably* does not alter the course of the disease Simple excision and adequate drainage usually suffice for treating clostridial cellulitis Penicillin is the antibiotic of choice for all clostridial infections and should be administered in doses of at least 20 million units a day Despite the fact that clostridial toxins are rapidly fixed in the tissues and cannot be demonstrated in the blood early treatment with antitoxin appears to reduce the mortality from gas gangrene complicating war wounds It is recom*mended that 50 000 units of polyvalent gas gan*grene antitoxin be given every 4 to 6 hr to all patients with suspected gas gangrene or clostridial postabortal sepsis The use of clostridial toxoids for prophylactic immunization of individuals in hazardous occupations awaits evaluation

Intravenous infusions of blood plasma volume expanders fluids and electrolytes are often required to combat shock anemia and dehydration Renal insufficiency should be treated in the same manner as acute tubular necrosis from other causes (see *p 1367*)

contact with infected material Tuberculous food handlers for example may deposit organisms on food or eating utensils which are then placed in the mouths of uninfected subjects Similarly tuberculous sinuses and urine and feces may occasionally be sources of infection Kissing is an example of transmission by direct contact and is probably an important source of infection in infants Dogs are susceptible to both the human and the bovine bacillus and may occasionally transmit tuberculosis Cats are said to be highly resistant to the human type of bacillus but susceptible to the bovine form Placental transmission of tuberculosis in the human occurs but is rare

The various sources of infection described above apply chiefly to the human bacillus which is responsible for over 95 per cent of tuberculous infections in this country The intensive campaign to destroy tuberculous cattle and to encourage pasteurization of milk has practically eliminated the milk borne bovine type of tuberculosis in the United States In some countries ingestion of contaminated milk is still responsible for a large number of cases of cervical adenitis and abdominal tuberculosis in infants and children Infection of the lungs by the bovine bacillus is uncommon even in areas in which it is responsible for a high incidence of intestinal tuberculosis The tubercle bacillus is destroyed by boiling in water for 2 min or by pasteurization at 60 C for 20 min

PATHOLOGIC ANATOMY

This subject is considered exhaustively in text books of pathology a brief summary will provide adequate reorientation for the purposes of this discussion In general two types of tissue response predominate in tuberculosis—exudative and productive According to Pinner exudative reactions tend to occur in association with loose tissue structure large doses of highly virulent organisms and bronchogenic spread to parenchymal tissues Productive reactions are commonly observed with small doses low virulence and firm tissue structure and in lesions in interstitial tissues resulting from hematogenous dissemination

In the exudative lesion in the lung polymorphonuclear leukocytes large mononuclear cells and fibrin infiltrate the alveolar spaces After a variable period of time this pneumonic type of lesion may undergo partial or complete resorption or it may caseate If caseation occurs areas of caseous pneumonia become liquefied a process which leads to cavitation with leukocytes and exudative material being expelled as sputum Caseous areas may also be replaced gradually by fibrosis and calcification It should be emphasized that the exudative reaction may be misdiagnosed easily even by histologic examination since epithelioid cells Langhans giant cells and caseation may be absent

The productive lesion or *tubercle* involves growth of new granulation tissue supported by a definite reticulum which pushes the normal tissue aside The tubercle consists of Langhans giant cells epithelioid cells and a surrounding layer of lymphocytes Later the granulation tissue making up the tubercle forms a fibrous capsule around the periphery differing in this respect from the exudative lesion in which the surrounding fibrosis is produced by collagenous tissue normally present in the peribronchial perivascular and septal spaces Productive lesions rarely undergo resolution to the extent observed with exudative lesions

Rarely primary tissue necrosis may occur in tuberculous infection This is observed in the so called acute caseating miliary tuberculosis and presumably results from the sudden hematogenous dissemination of large numbers of tubercle bacilli in extremely hypersensitive individuals

IMMUNITY

Native Resistance Man possesses a relatively high degree of native resistance to tuberculosis as manifested by his ability to arrest the infection in the great majority of instances Susceptible animals such as the guinea pig have little resistance and almost invariably succumb to the disease There are probably no differences in actual native resistance among white races the higher mortality rate of city-dwelling Irish as compared with Jews is probably due to natural selection of resistant individuals among the latter Negroes and Indians possess distinctly lower native resistance than whites Resistance is influenced by age and sex examples are the high mortality rate in infants and in females during the child bearing period The effect of environmental influences such as poor nutrition and overcrowding is clearly demonstrated by the close correlation of tuberculous mortality with economic and hygienic alterations during war time

Acquired Resistance Koch observed that cutaneously inoculated guinea pigs developed an indolent ulcer at the local site with rapid spread to and marked enlargement of the regional lymph nodes and eventual death from generalized tuberculosis In contrast animals previously infected developed an intense local skin reaction within a day or two followed by ulceration and healing Spread from the local site was greatly inhibited and there was little involvement and enlargement of the tributary lymph nodes Subsequent studies have confirmed and elucidated the chief characteristics of the lesion of reinfection in animals and man namely (1) an intense local inflammatory

death rate has fallen from 70 to 10 per 100 000 persons while the new case rate has declined only from 100 to 60 Thus the situation has reached the point where the mortality rate is no longer an accurate index of the prevalence of tuberculous infection The large number of new cases discovered each year (over 75 000) indicates that many individuals with undiagnosed active tuberculosis are still at large in the community Of the estimated 350 000 cases of active tuberculosis in the United States today 125 000 remain unrecognized

The tendency for tuberculosis to occur among older age groups deserves special mention In only 20 years the percentage of newly discovered cases in individuals under the age of thirty has dropped from more than 50 per cent to 20 per cent During the same period the percentage of patients in tuberculosis hospitals who are over sixty years of age has increased from 6 to almost 25 The rate of newly reported active cases of tuberculosis among men is nearly twice that among women in patients over fifty years of age the ratio is 4 1 Homeless alcoholic men make up a large proportion of the new cases

ETIOLOGY

Three types of tubercle bacilli—human bovine and avian—are known to infect man The last is of least importance only a small number of proved cases of avian infection have been reported in humans Morphologic and cultural differences between the three types are somewhat variable and animal inoculation is resorted to for positive identification The human type causes disease in the guinea pig but not in the rabbit the bovine type in both the guinea pig and the rabbit and the avian type in birds and rabbits but not in the guinea pig

The tubercle bacillus is about 1 0 to 4 0 μ in length and 0 3 μ in thickness Beaded and granular forms have been observed with both modified Gram and acid fast stains but recent evidence indicates that many of these are artefacts of the staining process True granular forms do occur particularly in older cultures and are identified by their red rather than purple color lack of distention of the cell wall and failure to disappear with the addition of alcohol Evidence for a filtrable virus or zoogleic stage in the life cycle of the tubercle bacillus is not entirely convincing for the present it must be assumed that reproduction occurs by fission The distinguishing tinctorial property of the tubercle bacillus—namely its ability to resist decolorization by acid alcohol when stained with basic fuchsin—is known to be related to the waxy component and probably specifically to mycolic acid Curiously the structural integrity of the cell is also involved for grinding the bacilli between glass slides destroys acid fastness whereas prolonged extraction with fat solvents does not alter this property

Avirulent dissociates of virulent strains of tubercle bacilli may be produced by appropriate cultural techniques and occasionally tubercle bacilli of unusually low virulence for laboratory animals have been isolated from man It has not been definitely established however that true dissociation can occur in the human body A simple morphologic differentiation between virulent and avirulent dissociates has been described by Middlebrook and Dubos—namely that virulent cultures grow in long tightly formed cords with individual bacilli parallel to each other whereas avirulent organisms are haphazardly arranged The correlation between cording and virulence is not absolute however

Chemically the tubercle bacillus is unique in its high lipid content which makes up one fourth to one third of its dry weight The lipids are composed of phosphatides acetone soluble fats and waxes These substances probably account for the unusual resistance of the tubercle bacillus to bactericidal agents to drying and to wide temperature variations They are not however as was once thought situated on the surface of the cell as a thick capsule but are distributed throughout the body of the bacillus

Tubercle bacilli are strict aerobes and are usually isolated on solid media containing potato egg yolk and glycerin Growth is slow 4 to 6 weeks being required for colonies to develop Because of their high lipid content tubercle bacilli are hydrophobic and grow in clumps on the surface of ordinary liquid media Dubos has developed a liquid medium containing a complex ester of oleic acid Tween 80 which coats the bacilli making them hydrophilic and provides rapid diffuse submerged growth This medium has become a standard tool for quantitative laboratory studies

TRANSMISSION

Inhalation of air containing tubercle bacilli is the most important means of acquiring tuberculous infection in man The bacilli may be transmitted in droplets of saliva or sputum Transmission may occur also from inhalation of particles of dust laden with viable organisms a method which is possible because of the peculiar resistance of the tubercle bacillus to desiccation and exposure Tubercle bacilli are killed within a few hours in direct sunlight but survive up to 5 days in a well lighted room up to 5 months in the dark and as long as a year and a half in the refrigerator

In addition to inhalation tubercle bacilli may enter the mouth and pharynx by direct or indirect

gins Seeding is common in the upper parts of the lungs producing lesions which appear in x rays as small indistinct areas of increased density These foci tend to heal with fibrosis and calcification Focal hematogenous lesions in other organs may regress and heal or they may lie dormant for many years and eventually cause progressive destructive lesions

Reinfection Tuberculosis Tuberculosis in the adult is regarded as usually being reinfectious in character i e infection in individuals whose immunologic state and tissue response have been altered by previous contact with the tubercle bacillus The basic manifestations of this altered response are as indicated in the section on Immunity an intense local inflammatory reaction suppression of proliferation of the bacilli and inhibition of their spread These features are observed in cases of reinfection tuberculosis in human beings just as they are in experimental animals in the Koch phenomenon in fact adult reinfection pulmonary tuberculosis (phthisis) is in essence as pointed out by Pinner a Koch phenomenon in the lung There is an intense local reaction of the tissues with a tendency to chronicity marked fibrosis excavation and restriction in the involvement of lymph nodes

Reinfection tuberculosis in the adult usually begins as a small caseopneumonic focus in the posterior portion of the upper lobe less commonly it may be present in the apical portion of a lower lobe While the patient is still asymptomatic this lesion can often be seen as a small area of density with indistinct borders in the infraclavicular region between the first and third anterior ribs This focus is commonly referred to as an *early infiltrate*

One of the unsolved problems of tuberculosis is the source of the tubercle bacilli which are responsible for the early infiltrate There are two possibilities One is inhalation of bacilli from without giving rise to an entirely new infection in the upper portion of the lung—i e the establishment of a true exogenous reinfection The other possibility is local exacerbation or transmission to the local site of bacilli which have lain dormant somewhere in the body following subsidence of the primary infection this is known as endogenous exacerbation The relative frequency with which exogenous reinfection and endogenous exacerbation are responsible for the early infiltrate is not known both undoubtedly occur

Adult tuberculosis as discussed in the preceding paragraphs is assumed to be largely reinfectious in nature It should be stated again however that an increasing number of cases of adult tuberculosis are instances of primary infection and unequivocally exogenous in origin

Pulmonary tuberculosis in the adult usually but not invariably begins as an early infiltrate In an occasional instance tuberculous pneumonia may follow the rupture of a caseous hilar lymph nod this is seen with increasing frequency in older individual Clinically suggestive evidence also indicates that pneumonic lesions may develop when a large inoculum of bacilli is carried suddenly to a portion of the lung from some endogenous focus Contiguous spread from nodular foci at the extreme pulmonary apex a mode of development thought at one time to account for virtually all phthisis unquestionably occurs in some cases Finally hematogenous seeding may give rise to bilateral foci usually in the upper parts of the lungs which remain interstitial and cause relatively few symptoms or ulcerate through the bronchi and gradually produce bronchogenic phthisis

Once formed the early infiltrate may regress and heal completely This may occur in ambulatory asymptomatic individuals but the value of bed rest in aiding this process is well established All too often the early infiltrate progresses to the characteristic chronic destructive form of pulmonary tuberculosis Caseation is followed by liquefaction and cavitation Intrabronchial aspiration gives rise to new parenchymal foci where the process is repeated The presence of bacilliferous sputum also leads in a large percentage of cases to lesions of the bronchial and tracheal mucosa Reparative processes supervene with resorption and fibrosis but the nature of the lesions especially the cavities which continually discharge infective material into the bronchial passages tends to foster chronicity and gradual extension of the disease

As pulmonary tuberculosis progresses increasingly large numbers of tubercle bacilli are expelled in the bronchopulmonary secretions and are responsible for lesions in the larynx the mouth and the intestinal tract The pathogenesis of other forms of extrapulmonary tuberculosis may be stated briefly Tuberculosis of the kidneys epididymis prostate fallopian tubes adrenals bones brain eyes lymph nodes and other organs not in direct contact with the external environment is lymphohematogenous in origin Seeding of these organs may occur during the active primary stage of infection causing progressive destructive lesions at that time or after many years of latency Hematogenous dissemination may also occur during reinfection tuberculosis in adults The internal organs vary considerably in their susceptibility to tuberculous infection Some such as those listed above are relatively frequently involved while others including the pancreas thyroid ovary spleen heart liver and skeletal muscles are rarely the site of progressive lesions

reaction which develops much more rapidly than with the primary infection (2) suppression of multiplication of the organism and (3) inhibition of spread of the bacilli with little or no involvement of the regional lymph nodes and a greatly decreased tendency toward hematogenous dissemination

Tuberculin hypersensitivity appears at approximately the same time as acquired resistance from 2 to 6 weeks following the initial infection The two are closely associated although the degree of hypersensitivity is not a measure of immunity In man a definite but limited degree of acquired resistance occurs as a result of a primary infection

Mechanisms of Resistance The basic mechanisms underlying native and acquired resistance to the tubercle bacillus are unknown Native resistance seems to be determined by conditions existing within the mononuclear phagocytes in which large numbers of tubercle bacilli become segregated soon after entering the body In the susceptible body bacilli multiply freely in the monocytes while in the natively resistant body the environment is for some unknown reason unfavorable causing the organisms to be inhibited and gradually to die

In acquired resistance humoral immunity has not been found to play the important role it does in most other infections Humoral antibodies have been demonstrated repeatedly in animals and patients infected with the tubercle bacillus but they appear irregularly do not increase the resistance of normal animals to tuberculosis and have not been found in vitro to render tubercle bacilli more easily phagocytable by opsonization

Lurie has observed an increased metabolic activity of phagocytes in natively resistant or immunized rabbits and studies indicate that hormones may play an important role in immunity Genetically susceptible rabbits have been found to secrete about twice as much hydrocortisone as animals which are genetically resistant These observations may lead to a better understanding of immunity in tuberculosis

PATHOGENESIS

Primary Tuberculosis Most tissues exposed to direct contact with bacilli are protected by local mechanical defenses under ordinary circumstances but may become infected when these defenses are broken Thus the primary focus is observed occasionally on the fingers on ear lobes that have been pierced on the tonsils and on the conjunctiva

In the lung the primary focus is usually near the pleura and occurs most frequently in the upper part of the lower lobe or the lower part of the upper lobe Initially exudative in character the primary focus rapidly undergoes caseation Tubercle bacilli escape freely and are carried to the bronchopulmonary and tracheobronchial lymph nodes which become greatly enlarged and undergo exudation and caseation The combination of the primary focus and the enlarged regional lymph nodes is commonly referred to as the *primary complex*

It has become increasingly common for individuals to attain adult life without contracting a primary tuberculous infection It is a curious fact however that in white adults it is unusual to observe the x ray enlargement of the tracheobronchial lymph nodes so characteristic of primary infections in childhood Both from the standpoint of x ray appearance and clinical course lesions in recently tuberculin negative adults are indistinguishable from those clearly due to reinfection tuberculosis Exceptions have been observed but are uncommon In Negroes typical primary complexes are observed in adults as well as in children This racial difference suggests that an age determined native resistance may modify the characteristics of primary infections in white adults while in Negroes who have a lower degree of native resistance the age determined difference is lacking

Deviations from the classic primary complex have been described by Terplan The parenchymal focus and the lymph node component have been observed to occur separately and new typical primary complexes have been noted in lungs in which the true initial complexes are in a relatively advanced state of healing

In the great majority of instances the primary complex undergoes gradual healing with encapsulation of the parenchymal and lymph node components and eventual calcification By x ray the lesions gradually recede from the periphery and eventually leave small areas of calcific density usually less than 1 cm in diameter Bacteriologically in over 80 per cent of adults who have arrested a primary infection in childhood the calcified primary complex is sterile In these instances the possibilities of endogenous exacerbation are not completely excluded however for tubercle bacilli may remain viable in lesions of the paratracheal or upper mediastinal nodes

In a small percentage of cases there is progression of the primary complex this accounts for most of the fatalities in infants and children Progression occurs in the following ways (1) direct extension or intrabronchial spread (2) massive lymph node caseation with rupture into a bronchus resulting in tuberculous pneumonia and (3) hematogenous dissemination Hematogenous dissemination occurs frequently during the course of primary tuberculosis and may result in the full blown picture of miliary tuberculosis with death in a few weeks or may merely give rise to seeding in various or

Occasionally a gross hemoptysis may usher in the disease the patient being unaware of any previous symptoms Bleeding results usually from the ulceration of vessels in tuberculous cavities and the natural tendency of the infectious process to cause vascular thrombosis is an important factor in preventing massive hemorrhages in the majority of patients with cavitary disease Large hemoptyses usually occur without warning and frequently begin when the patient is asleep Ordinarily not more than 300 ml of blood is produced Dark clots of blood are usually brought up for several days if the cough mechanism is inadequate there may be blockage of a main bronchus with collapse of one or more lobes Bleeding may recur at frequent intervals and transfusions may be needed In an occasional instance the hemorrhage is massive and fatal this usually occurs with old fibrotic disease and the patient drowns within a few minutes One of the greatest hazards of hemoptysis is the danger of spreading the infection throughout the lungs Depending on the number of tubercle bacilli present in the bloody fluid posthemoptysic spreads vary in extent from scattered finely mottled infiltrations to massive tuberculous pneumonia

As pulmonary tuberculosis progresses and especially with cavitary disease ulcerations or granulomatous infiltrations frequently appear in portions of the tracheobronchial tree draining affected lung tissue with *wheezing* as a common symptom Endobronchial disease may alter the treatment and therefore this symptom should be carefully sought for Wheezing may also occur in the absence of demonstrable ulcerations or granulations and is then presumably caused by mucosal swelling or retained secretions It should be noted that tuberculous tracheobronchitis occasionally occurs in the absence of demonstrable parenchymal disease

Tuberculous Pneumonia The clinical onset of tuberculosis occasionally may be an acute pneumonic episode especially in Negroes in children and in elderly individuals both white and colored The sudden aspiration of a dose of bacilli sufficiently large to cause a pneumonic lesion results usually from the abrupt emptying of a cavity from a hemoptysis or from the rupture of a caseous node into a bronchus Fever chilly sensations cough and chest pain are noted and the condition can easily be confused with primary atypical pneumonia The temperature is usually not above 102 F though it may rise to 104 or 105 F and the white blood count is in most instances not elevated above 15 000 Untreated tuberculous pneumonia may run a malignant course with death in from 1 to 3 months or the process may gradually subside and become chronic

Pleurisy with Effusion This condition is common among young adults and its pathogenesis and significance need emphasis The pleura usually becomes involved as a result of direct or lymphatic extension from an underlying parenchymal process and the lesion in the lung often is not of sufficient size to be visible on the x ray Whether the pleura can also be infected directly by way of the blood stream is a matter of dispute Animal experiments indicate that parenteral injections of tubercle bacilli rarely result in direct infection of serous cavities The not infrequent occurrence of bilateral effusions on the other hand is often cited as evidence that infection of the pleural surfaces may result from direct hematogenous seeding Chest pain and fever are the initial symptoms the pain may be sharp and pleuritic in character or it may begin as a dull ache or uncomfortable sensation in the lower chest In the more acute cases there is marked prostration with a high fever and a stormy course for 2 or 3 weeks More commonly the temperature is only moderately elevated and the patient does not feel particularly ill except for the pain in the chest Clear yellow fluid is obtained by aspiration and tubercle bacilli are recovered by culture or guinea pig inoculation in approximately 50 per cent of the cases Whether the organism is recovered or not experience has shown that without treatment 30 to 50 per cent of the patients develop clinical and x ray signs of active pulmonary tuberculosis within 5 years These figures are sufficiently high to warrant the assumption that all cases of "nonspecific" pleurisy with effusion are caused by tuberculosis and they should be treated accordingly Details of management will be outlined in a subsequent section

Physical and X ray Examination

The widespread use of the x ray during the past 25 years has demonstrated the marked limitations of physical examination in detecting and appraising the lesions of pulmonary tuberculosis As a result the tendency at present in many quarters is virtually to ignore the physical examination altogether this is lamentable for the physical signs contribute information which when correlated with the x ray findings gives a more complete understanding of the nature and activity of the parenchymal disease

Early asymptomatic infiltrations are usually missed on routine physical examination and indeed it is often surprising how extensive the x ray infiltrations may become before definite physical abnormalities are detected Crepitant posttussic rales may be noted over a small area in minimal lesions although rales are not of themselves conclusive evidence of activity With larger lesions especially after cavitation develops dullness and moderately coarse rales are usually elicited With pneumonic lesions the classic signs of consolidation are noted

PULMONARY TUBERCULOSIS

Manifestations

The onset of symptoms of pulmonary tuberculosis is in many instances *insidious* In the early stages and at times when moderate progression has occurred the patient is usually *entirely asymptomatic* and may remain so for a considerable period This cannot be emphasized too strongly more and more early asymptomatic cases are being discovered as a result of routine films and x ray surveys

The earliest symptoms are constitutional and probably result chiefly from the absorption of tuberculoprotein into the circulation of the hypersensitive body *Fever* is one of the commonest manifestations of tuberculosis and usually begins as a slight elevation of the temperature in the late afternoon or evening This elevation may occur daily gradually attaining higher levels over a period of weeks or months or it may subside altogether and reappear intermittently as the patient passes through a series of grippelike episodes It is characteristic for fever to be relatively well tolerated in patients with tuberculosis even with a temperature elevation to 102 or 103 F Except for sensations of warmth and flushing the patient is often quite comfortable and in some instances is even euphoric

Fatigue and malaise are among the earliest symptoms noticed by the patient They usually first manifest themselves as excessive tiredness at the end of the day and may lead the patient to restrict his activities in the evening in order to get more rest In other instances particularly when the subject refuses to modify his routine he may become irritable and morose Eventually in far advanced disease profound asthenia is often present

Weight loss is usually noted somewhat later than the above symptoms and may not be present for many months unless the disease runs a malignant course Anorexia and indigestion are associated symptoms and seem to vary with the severity of the other manifestations Anorexia may provide a clue from the standpoint of differential diagnosis tuberculosis at this stage can be confused with diabetes and thyrotoxicosis and in both these conditions loss of weight is characteristically associated with an increase in appetite

Chilly sensations may be noted as the toxemia progresses particularly when the temperature rises abruptly in the evening *Night sweats* are considered classic manifestations of tuberculosis but actually do not occur in most instances until the disease is fairly far advanced *Tachycardia* occurs along with the fever *Headache* is noted in some individuals in the evening when the temperature is elevated but the symptom usually subsides by morning and is absent during the daytime

Menstruation is said to be disturbed in tuberculosis but this statement is based upon the situation occurring in far advanced disease In the early stages the menses are usually normal and become irregular and scanty only as the disease progresses Amenorrhea may occur in the later stages particularly when the condition becomes terminal For reasons not entirely clear hemoptysis seems to occur more frequently during the menstrual period

Since examination of the lungs in the early stages is negative in most instances and the blood count and sedimentation rate may be entirely normal the importance of the chest x ray in diagnosis cannot be overemphasized

In many patients with pulmonary tuberculosis the onset of symptoms is *relatively sudden* A characteristic story is that of a bad cold or "influenza without awareness of any prior disability The cold—especially the cough—persists while the constitutional manifestations may subside temporarily giving the patient the feeling that he is recovering Some individuals may recall a slight morning cough of some months duration attributed usually to irritation from smoking Cough is characteristically first noted in the morning because secretions formed in the lungs during the night flow into the bronchi and trachea and stimulate the cough reflex on arising Once these passages are cleared the patient coughs infrequently or not at all until the next morning when another mild paroxysm occurs As the disease progresses the secretions are formed in larger amounts and the cough becomes more troublesome occurring throughout the day and night

Along with cough there is expectoration of *sputum* In early cases a few flecks of pus may be seen in the mucus and later the sputum becomes predominantly purulent in character As cavitation progresses liquefied caseous material is formed in increasing amounts until 2 or 3 oz of sputum are produced daily In caseous pneumonic lesions with cavitation and liquefaction the purulent matter is usually green or greenish yellow Later as the clinical condition improves the sputum is yellowish and more mucoid Tuberculous sputum is not foul except in rare instances in which the pulmonary lesions become secondarily infected with anaerobes Layering does not usually occur a feature which is at times helpful in differentiating tuberculosis from lung abscesses Late in the course of the disease secondary infection of tuberculous cavities does occasionally occur and the patient may become exhausted by his efforts to bring up 300 or 400 ml of sputum daily

Hemoptysis is commonly associated with cough and expectoration and ordinarily consists of streaking of the sputum with small amounts of blood

to 1 0 mg OT Recent evidence indicates that the *second strength sometimes gives false positive re* actions and the present trend is towards using a single intermediate strength concentration of P P D namely 0 001 mg

The tuberculin patch test is often used in chil dren to avoid the use of needles It is less reliable however and if negative should be followed by the intracutaneous test if an accurate appraisal of the skin reactivity is desired

Laboratory Findings

Recovery of Tubercle Bacillus Aside from the x ray the most important laboratory procedures used in the diagnosis and management of patients with tuberculosis are those concerned with the isolation of tubercle bacilli from sputum gastric wash ings urine feces spinal fluid serous and purulent effusions abscesses and draining sinuses

Sputum may be absent or present in only small amounts early in the morning in patients with mini mal tuberculosis and a few flecks of mucopurulent material obtained at this time may be adequate to make the diagnosis The material is usually exam ined first by the direct smear The Ziehl Neelsen method of staining is the most widely used al though a fluorescent dye carbolauramine has be come popular in recent years Fairly large numbers of tubercle bacilli must be present to be seen on the direct smear Therefore if this is negative 20 ml or more of sputum is collected digested with acid or alkali concentrated by centrifugation neu tralized and the sediment smeared stained and examined With this technique a significantly higher percentage of specimens is positive than on direct smear If negative on smear the concentrated sedi ment is cultured or inoculated into guinea pigs or both Twenty to thirty per cent more positives are obtained by culture or guinea pig inoculation than by smear of the concentrated sediment The rela tive merits of cultures and guinea pig inoculations are debated but the results with cultures are so favorable that in many laboratories the more la borious and expensive guinea pig method has been abandoned

If no sputum is produced the *gastric contents* should be aspirated shortly after the patient awak ens in the morning Smears of the gastric contents may give false positive results therefore the ma terial is digested concentrated and cultured or inoculated into guinea pigs In minimal cases of pulmonary tuberculosis prior to the development of cavitation discharges carried into the bronchial tree and swallowed by the patient are small in amount and many cultures of the gastric contents may be necessary to recover tubercle bacilli For example in one study it was found that 68 per cent of minimal cases had at least 3 negative speci mens before a positive was obtained and in another series of 61 patients from 5 to 14 negatives were reported prior to the first positive culture Once cavitation develops the discharges increase in amount and bacilli can be recovered by cultures of the sputum or gastric contents with comparative ease A series of negative sputum or gastric cul tures in the presence of cavitation provides strong presumptive evidence against the diagnosis of active pulmonary tuberculosis

The basic principles outlined for sputum and gastric contents apply to the recovery of tubercle bacilli from other sources Minor modifications are necessary especially in preparing and concentrat ing urine and stool specimens With spinal fluid tubercle bacilli are often detected by smear or cul ture of the pellicle which forms if the specimen is left in the icebox overnight

Sedimentation Rate The sedimentation rate is normal in the majority of individuals with minimal tuberculosis In more advanced febrile cases the sedimentation rate usually is elevated and often is used as an index of the progression or regression of the disease This use has definite limitations how ever since the rate may be normal in patients on absolute bed rest in spite of progressive intrabron chial disseminations and conversely a sudden in crease in the rate may accompany the onset of a relatively insignificant complication such as mild pleurisy

Blood Hematologic changes in tuberculosis are relatively slight In minimal cases the blood count is usually normal but as the disease progresses there may develop a mild normochromic normo cytic anemia Even in far advanced cases the anemia usually is not marked except in the pres ence of extrapulmonary complications such as in testinal tuberculosis or amyloidosis A mild leuko cytosis may be present in progressive febrile stages with a count of 10 000 to 15 000 but even in acute tuberculous pneumonia the total white count is rarely above 15 000 An increase in monocytes with a decrease in lymphocytes is regarded by some ob servers as indicative of progression of the disease and in experimental animals this appears to be well substantiated In man however the lymphocyte monocyte ratio and other prognostic guides such as the Medlar index are of limited value Exceptions to some of the above statements should be noted in widespread acute tuberculous pneumonia for ex ample the total white count may occasionally be well above 20 000 with a polymorphonuclear count of over 95 per cent Similarly in acute miliary tu berculosis there may occur a high grade leukocy tosis and at times even a leukemoid blood picture or there may be a marked leukopenia

Urine Changes in the urine in pulmonary tu berculosis as in other chronic febrile diseases con

and as cavitation develops coarse bubbling rales appear especially at the base of the cavities where liquefied pus tends to accumulate Even with large cavities demonstrable on the x ray however the classic signs of tympany and amphoric breathing are often absent because the soft shaggy cavity walls and surrounding structures do not act as good resonators In old fibrocaseous lesions the walls are relatively thick and rigid and the classic signs of cavitation may be present Tension cavities associated with bronchial disease preventing normal egress of air during expiration also produce atypical signs With long standing disease extensive fibrosis causes contraction and distortion of the pulmonary tissue In such instances a wide variety of physical signs such as bronchial breath sounds coarse rales deviation of the trachea spasm and atrophy of various chest and neck muscles and diminished movements of one hemithorax are noted

From an x ray standpoint the early infiltrate is usually observed in the infraclavicular region although it may be located entirely above the clavicle or in the midlung field As the infiltrations progress and enlarge the x ray appearance of pulmonary tuberculosis may be indistinguishable from various nontuberculous conditions Tuberculous cavities especially when located in the lower lung fields closely simulate nontuberculous lung abscesses Similarly the tuberculous nature of bronchopneumonic or lobar consolidations cannot be determined on the basis of the x ray alone The limitations of a single film in determining whether an infiltration is tuberculous and of assessing its activity leads to serious diagnostic and therapeutic errors

Aside from its diagnostic limitations the x ray film may at times give misleading impressions concerning the functional status of the lungs For example in patients who have had pleural effusions or extensive nodular bronchogenic disseminations following hemoptysis the lung fields may eventually become almost entirely clear by x ray although pulmonary function remains markedly impaired Careful physical examination will reveal the presence of impaired function in such cases and will lead to more precise pulmonary function studies if surgery is contemplated

Tuberculin Test

Tissue hypersensitivity to tuberculoprotein results from the production of tuberculous tissue in the body by intact whole tubercle bacilli either living attenuated or dead A positive tuberculin test indicates therefore that an individual has or has had such a focus of tuberculous tissue in his body It does not indicate that he harbors a clinically significant lesion or that any of his present signs or symptoms are necessarily due to tuberculosis active or inactive The chief value of the test lies in exclusion If negative it can be fairly reliably concluded that the patient does not have active tuberculosis virtually all individuals with active tuberculosis have a positive tuberculin reaction Exceptions are sometimes noted during the course of intercurrent infections especially measles and influenza late in the course of pregnancy and in some terminal cases of tuberculosis The tuberculin skin reaction may turn negative after a period of years in individuals who have arrested and healed a primary tuberculous infection the frequency with which this occurs is not known but many well documented instances are on record The increasing incidence of negative tuberculin reactions in young adults has enhanced the diagnostic value of the test in recent years Only 20 to 30 per cent of young men in the Armed Forces during World War II were tuberculin positive in this age group the skin reaction is particularly helpful in ruling out tuberculosis in the presence of obscure fevers and undiagnosed pulmonary conditions

The most reliable and accurate method of performing the tuberculin test is the intracutaneous or Mantoux test in which 0 1 ml of suitably diluted tuberculin is injected intradermally into the skin of the forearm If positive induration (5 mm or more) appears at the local site in 24 to 72 hr and is surrounded by an area of inflammation varying from one to several centimeters Intense local reactions occur if the dose of tuberculoprotein is too large causing tissue necrosis and lymphangitis extending to the regional nodes Absorption of tuberculoprotein into the circulation of the highly hypersensitive body causes constitutional symptoms chiefly malaise and fever and may produce focal reactions around tuberculous lesions throughout the body To avoid these untoward reactions small doses of tuberculin should be used for the initial test with gradually increasing amounts thereafter at intervals of 3 or 4 days until the test becomes positive If old tuberculin (OT) is used the initial dose is usually 0 01 mg (0 1 ml of a 1 10 000 dilution) in individuals suspected of being unusually hypersensitive the initial dose may be reduced to *0 001 mg If the reaction is negative tenfold incre*ments in the amount of OT are employed for subsequent tests An individual is ordinarily considered tuberculin negative if he fails to react to 1 0 mg although some observers prefer to increase the amount to 10 mg In recent years the purified protein derivative (P P D) of Seibert has partially replaced OT because it gives more uniform results and minimizes false positive reactions It is available commercially in two strengths the first (0 00002 mg) being roughly equivalent to 0 01 mg OT and *the second (0 005 mg) corresponding*

exposure the coccidioidin skin test smears and cultures of the sputum for *Coccidioides immitis* and precipitin and complement fixation tests of the patient s serum are the procedures used in con firming or excluding the diagnosis *Histoplasmosis* recently has been suspected of causing pulmonary calcifications similar to those occurring in tubercu losis because of the observation that many indi viduals in the South Central states with pulmonary calcifications have positive histoplasmin skin tests and negative tuberculin reactions Other mycotic infections such as *actinomycosis* and *blastomycosis* may at times simulate tuberculosis but the fungi involved usually can be readily recovered from the sputum

Sarcoidosis Typically the patient with sarcoido sis is afebrile and has a negative tuberculin test and biopsy of lymph nodes reveals tubercles without caseation Fever may be present however and in about 20 per cent of cases the tuberculin test is positive Pulmonary infiltrations vary from hilar adenopathy to extensive parenchymal involvement which can resemble tuberculosis very closely In some cases differentiation is extremely difficult and the situation is further complicated by the fact that some patients with a diagnosis of sarcoidosis eventu ally die of tuberculosis

Carcinoma of Lung Carcinoma of the lung with chronic cough blood streaked sputum fever and weight loss may present a clinical picture very simi lar to tuberculosis in older individuals Carcinomas located peripherally produce fewer symptoms but may present an x ray appearance indistinguishable from that of tuberculosis Patients with lesions sus pected of being carcinomatous from whom tubercle bacilli cannot be recovered should be subjected to early thoracotomy It should be noted that both tuberculosis and carcinoma are occasionally present in the same patient

Cardiovascular Disorders These may produce symptoms suggestive of tuberculosis Hemoptysis occurs frequently with mitral stenosis and is occa sionally observed with hypertension Long standing pulmonary congestion such as occurs in patients with mitral stenosis causes pulmonary fibrosis in fected pulmonary infarcts may develop into ab-scesses suggestive of tuberculous cavitation

Other Conditions Mediastinal cysts bacterial pneumonia lipoid granuloma lymphomas ame biasis aortic aneurysms and metastatic neoplasms may be confused with tuberculosis Careful evalua tion and study including the exclusion of tubercu losis by the failure to find tubercle bacilli usually will lead to the correct diagnosis

Evaluation of Need for Treatment

In patients with progressive symptomatic pul monary tuberculosis the clinical and x ray findings are usually characteristic and the diagnosis and need for treatment are established readily In some situations however the diagnosis and degree of activity and therefore the need for treatment are more difficult to ascertain At the outset it may be stated that old calcified primary complexes nodu lar fibrotic areas at the extreme apices and ad hesions and scarring due to old pleurisy are not indications for treatment Individuals with these lesions should have yearly x ray examinations since dormant foci can give rise to active disease during periods of lowered resistance

Minimal infraclavicular infiltrations often de tected as a result of x ray surveys require careful evaluation which in most instances should be carried out with the patient at bed rest This is particularly true of individuals under twenty five years of age Hazy poorly circumscribed shadows indicate exudative unstable lesions while dense sharply circumscribed infiltrations usually represent old arrested disease which is unlikely to progress Serial x rays are the best means of following a lesion and determining its activity These should be made at least once a month and sometimes more frequently in young adults with exudative lesions Gastric washings should be cultured re peatedly Careful clinical observations and serial roentgenograms over a period of at least 6 months are usually adequate to determine the activity of the lesion Chemotherapy may be instituted at the outset if clinical and x ray findings indicate that the lesion is almost certainly active

Treatment

The advent of effective chemotherapeutic agents has brought about great changes in the treatment of tuberculosis during the past decade It is now generally agreed that all patients with active tu berculosis should receive prolonged chemotherapy and that bed rest is necessary for only part of the period of treatment Collapse therapy is being used less and less so that initial treatment for most patients consists of rest and the administration of antimicrobial drugs If after several months the sputum remains positive or if there are open cavi ties or large residual necrotic foci surgical excision of the involved areas is performed The basic prin ciples of therapy can thus be stated very simply but a great deal remains to be learned about the optimal indications for and details of bed rest chemotherapy and surgical management of the disease

Ten years ago it was agreed that *bed rest* was the most important single measure available for the therapy of tuberculosis The course of the dis ease is so changed by chemotherapy however that modifications of the formerly strict regimens are now employed Fever and toxicity are definite indi

sist chiefly of intermittent traces of albumin without other significant abnormalities Renal tuberculosis is not uncommon and frequent urine examinations should be made noting especially persistent proteinuria and an abnormal number of erythrocytes and leukocytes If these are present *pyelograms* are indicated and concentrated urine specimens should be cultured and inoculated into guinea pigs Except in rare cases an active renal lesion is present if tubercle bacilli are recovered repeatedly from the urine and drug therapy is indicated

Other Tests A number of serologic tests have been employed in tuberculosis but none has been found to be of practical diagnostic or prognostic value The complement fixation reaction for example is positive in less than 50 per cent of patients with minimal lesions and false positive reactions are obtained in over 10 per cent of individuals with no evidence of active tuberculosis

Differential Diagnosis

The onset and course of pulmonary tuberculosis *vary widely and may simulate a great number of* other diseases The outstanding conditions which may be confused with tuberculosis and the main differential features will be considered briefly

Psychoneurosis Patients with purely functional disorders frequently present complaints similar to those of early pulmonary tuberculosis Malaise easy fatigability and inability to concentrate are common symptoms and there may be anorexia with slight weight loss A chronic hacking cough may be present due to irritation of the respiratory passages from smoking A careful evaluation of these complaints will usually give a clue to the correct diagnosis A chest x ray is an essential part of the examination of patients with the symptoms described above

Endocrine Disorders Two endocrine disorders *hyperthyroidism* and *diabetes* are commonly manifested by weight loss and easy fatigability In contrast to tuberculosis however the weight loss is associated with an increased appetite rather than with anorexia Negative chest x rays in addition to glycosuria and an abnormal glucose tolerance test in diabetes and an elevation of the basal metabolic rate in hyperthyroidism lead to the correct diagnosis

Obscure Fevers Tuberculosis is always to be considered in the differential diagnosis of fevers of unknown origin With a negative chest x ray the fever may be caused by early miliary tuberculosis or by an extrapulmonary tuberculous focus and localizing signs should be sought for (see p 73)

Pulmonary Fibrosis and Emphysema Pulmonary fibrosis and emphysema with cough weakness dyspnea and at times streaking of the sputum are relatively common in older individuals Tuberculosis is in some cases the cause or is an associated condition and therefore the sputum should be examined carefully for tubercle bacilli Pneumoconioses especially silicosis should be kept in mind and the patient questioned concerning possible industrial exposure *Nodulation* more dense near the hilar regions and extending peripherally through both lung fields is the characteristic x ray appearance of silicosis With the development of a superimposed tuberculous infection larger confluent shadows appear and the constitutional manifestations of tuberculosis are usually present although it may be very difficult to recover tubercle bacilli from the sputum

Nontuberculous Lung Abscess This affection which may be roentgenologically indistinguishable from tuberculosis usually has an acute onset with chills fever and leukocytosis The sputum may or may not be foul depending on the organisms involved The differential diagnosis is usually relatively simple since acid fast bacilli are almost always readily demonstrable in patients with tuberculous cavities Clubbing of the fingers may develop in 4 to 8 weeks in the presence of a nontuberculous abscess Nontuberculous abscesses may become chronic and when seen at this stage especially in conjunction with hemoptysis may be very suggestive of tuberculosis Sputum studies plus a careful review of the original signs and symptoms usually will clarify the situation (see p 1394)

Bronchiectasis Bronchiectasis is usually associated with a chronic productive cough and is one of the commonest causes of hemoptysis Clubbing of the fingers is common while in tuberculosis it is rare Bronchiectasis usually involves the lower portions of one or both lungs but is sometimes situated at the apex The x ray may be completely negative or there may be increased linear densities extending outward and downward from the hilar regions Moderately coarse rales usually are noted over the involved areas The failure to find acid fast bacilli in the sputum and the demonstration of radiographic abnormality by bronchogram confirm the diagnosis Not infrequently tuberculosis and bronchiectasis are found to coexist

Primary Atypical Pneumonia This presents a clinical and x ray picture which may be indistinguishable from pulmonary tuberculosis The absence of cavitation the failure to find tubercle bacilli in repeated examinations of the sputum and the eventual complete clearing of the parenchymal lesions are the important differential features

Mycotic Diseases *Coccidioidomycosis* presents a clinical and x ray picture similar to pulmonary tuberculosis This condition is of national importance because of the large number of individuals who were in the endemic areas of the Southwest during the *Second World War A history of possible*

ability to produce tuberculin hypersensitivity With metabolically inactive organisms such as occur in poorly oxygenated lesions or after previous therapy isoniazid is taken up reversibly and does not interfere with acid fastness nor sensitizing ability These observations undoubtedly explain in part why tubercle bacilli are not often eradicated from tuberculous lesions in patients During therapy drug resistant organisms emerge quite rapidly and it is customary therefore to administer another antimicrobial agent simultaneously With isoniazid however the appearance of resistant mutants is not so clearly related to a failure to show continued improvement as it is with streptomycin This may be related to Middlebrook s observation that some isoniazid resistant tubercle bacilli do not form catalase and have little or no virulence when injected into guinea pigs Failure of these organisms to grow in tissues may be due to susceptibility to the toxic effects of hydrogen peroxide Catalase positive isoniazid resistant mutants which are fully virulent also occur and probably account for progression of the disease which is observed after isoniazid resistance has developed

Isoniazid is usually given orally in a total daily dose of 3 to 10 mg per kg body weight For adults the arbitrary selection of a daily dose of 200 to 300 mg given in divided doses at 8 or 12 hr intervals is satisfactory It has been shown however that some patients acetylate the drug at an unusually rapid rate and require 600 to 1 000 mg daily to provide adequate tissue concentrations These higher doses are used routinely in a few clinics When high doses are employed 50 to 100 mg pyridoxine should also be given daily to prevent peripheral neuritis (see p 826)

Drug Regimens It is generally agreed that with few exceptions two and sometimes three drugs should be administered simultaneously in the treatment of all forms of tuberculosis The exceptions apply to isoniazid which is probably adequate when used alone for the treatment of minimal pulmonary tuberculosis and tuberculous pleurisy with effusion Isoniazid is also used alone in some clinics for a year or two following an initial 3-month period of multiple drug therapy

Of the regimens available it has been definitely shown that those containing isoniazid produce superior results Thus the combination of streptomycin and PAS which was so widely used for a few years is now employed for initial therapy only under unusual circumstances Isoniazid PAS is probably most widely used for the initial treatment of pulmonary tuberculosis at the present time The results are comparable or nearly so to those obtained with any other combination and both drugs are taken by mouth Another important advantage is that streptomycin is held in reserve for use later in conjunction with surgery if it is needed With this combination the effective blood levels of both drugs are higher than when either is given alone possibly because isoniazid and PAS compete for the same acetylation mechanism

Results with isoniazid streptomycin are perhaps slightly superior in far advanced cases to those obtained with isoniazid PAS particularly when streptomycin is injected daily rather than twice a week The chief disadvantage namely that the two most potent drugs are likely to become ineffective because of the development of resistant organisms is not of great importance since the relapse rate is only about 5 per cent Furthermore the combination of viomycin PAS is available if needed for surgical coverage In older individuals who are more susceptible to the toxic effects of streptomycin some experts prefer to avoid this drug and to select isoniazid PAS instead it is apparent from what has been said that both isoniazid PAS and isoniazid streptomycin have their advantages and it is desirable to select the combination most suitable for each individual patient The use of three drugs simultaneously (isoniazid streptomycin and PAS) has not been found superior for the treatment of pulmonary tuberculosis For certain extrapulmonary forms of the disease to be considered later triple-drug regimens are commonly used

Duration of Chemotherapy The optimal duration of therapy cannot be stated at present The most important trend to be noted is a gradual lengthening from 2 to 3 months in the years prior to 1949 to regimens which call for 1 to 2 years of drug therapy Combined therapy with its lower incidence of toxicity and delay in development of bacterial resistance has been chiefly responsible for the change It is clearly evident that the overall results are better with prolonged drug therapy It is probably safe to follow the policy of continuing drug therapy for at least 6 months after clinical and laboratory observations indicate that the disease has become inactive The minimal period should probably not be less than 12 months and 2 years seems a reasonable maximum There are patients however with extensive disease not amenable to surgical therapy to whom it may be wise to administer antimicrobial therapy indefinitely

Collapse Therapy This is another area in which older concepts have undergone radical changes At one time statistical studies of pulmonary tuberculosis invariably showed a worse prognosis in patients with open cavities than in those without cavitary disease Large cavities closed occasionally on bed rest alone but usually they did *not* and it was primarily in this type of case that artificial collapse therapy had its greatest usefulness Now

cations for bed rest After the first few weeks when the temperature has returned to normal sufficient rest to avoid fatigue may be all that is necessary Some authorities still maintain a much more conservative attitude insisting on complete bed rest except for bathroom privileges as long as the sputum is positive and chest x rays show continuing changes

With few exceptions treatment should be instituted in a *sanatorium* or in an isolation unit of a general hospital and the patient should remain there for at least a few months The chief advantages of hospitalization are that a careful program of daily activities can be carried out in a neutral environment under expert supervision and the patient s progress can be followed closely with both clinical and laboratory observations Other advantages are that the patient is removed from the community during the infectious period and opportunities for education orientation and rehabilitation are provided

Climate was at one time considered an important part of the treatment of pulmonary tuberculosis but the excellent results obtained in many different environments including hospitals in the busiest portions of our larger cities have made it apparent that climate exerts a relatively insignificant influence on the course of the disease Aside from the elements comprising a good well balanced *diet* no vitamins or other substances are known which specifically promote healing despite the enthusiasm of some for vitamin D ascorbic acid calcium etc The total caloric intake should be designed to enable the patient to regain and maintain his ideal weight

Chemotherapeutic Agents Factors affecting resistance which have been described above are often inadequate by themselves to control tuberculous infection The remarkable effectiveness of drugs in decreasing the number of tubercle bacilli so tips the balance in favor of the host however that many patients are now salvaged who would previously have succumbed to the disease

Three drugs are now in widespread use in the treatment of tuberculosis streptomycin para aminosalicylic acid (PAS) and isoniazid Other agents which may be used when these drugs are poorly tolerated or when bacterial resistance has developed are viomycin and oxytetracycline Viomycin is somewhat less effective than streptomycin and is quite toxic It has proved to be a valuable agent however when isoniazid and streptomycin are poorly tolerated or ineffective Oxytetracycline exerts a weak action but can be used in doses of 2 to 4 Gm daily if necessary as an alternative to PAS Two new drugs pyrazinamide and cycloserine are quite effective but are also toxic Cycloserine is toxic to the central nervous system and pyrazinamide to the liver The principal drugs will be considered separately and then the combinations used in therapy will be described

Either *streptomycin* or its hydrogenated derivative dihydrostreptomycin may be used Streptomycin was at first given alone and was effective for only 2 or 3 months because of the appearance of drug resistant tubercle bacilli It was then learned that the emergence of resistant organisms could be markedly delayed by the concomitant administration of PAS As a result the duration of effective drug therapy has been greatly lengthened For most patients with pulmonary tuberculosis 1 Gm twice weekly has been found to be as effective as the daily administration of the same dose For more serious forms of the disease such as miliary tuberculosis and tuberculous meningitis streptomycin is given every day at least for the first 2 or 3 months

Para aminosalicylic acid commonly referred to as PAS is a relatively weak tuberculostatic agent when used alone but is very effective in delaying the emergence of streptomycin resistant and isoniazid resistant tubercle bacilli The optimal regimen is unknown but the usual procedure is to administer 12 Gm daily by mouth in three or four doses Gastrointestinal irritation is common causing anorexia nausea vomiting and abdominal pain The sodium salt causes fewer reactions than the free acid and is the form of the drug most commonly used To administer 12 Gm of the free acid 16 5 Gm of the sodium salt must be prescribed A lyophilized preparation of the sodium salt is available for parenteral administration and as much as 30 Gm a day can be given intravenously without causing anorexia and nausea Serious toxic reactions are rare Dermatitis and drug fever are encountered occasionally and can usually be controlled by desensitizing the patient with increasing doses of the drug Para aminosalicylic acid is sometimes goitrogenic but thyroid enlargement from this cause can usually be prevented or ameliorated by the administration of desiccated thyroid This is rarely necessary The emergence of drug resistant organisms has been observed when PAS is given alone but is less common when it is administered with streptomycin

Isoniazid a derivative of nicotinic acid is more effective than either streptomycin or PAS in the treatment of experimental and human tuberculosis In contrast to streptomycin it penetrates mononuclear phagocytes and is active against intracellular as well as extracellular tubercle bacilli Like streptomycin isoniazid is bactericidal only against actively multiplying tubercle bacilli Under these conditions Koch Weser has shown that isoniazid is irreversibly bound to the organisms which after several days become non acid fast and lose their

but will serve to illustrate the principles employed and will emphasize the shorter period of hospitalization which is necessary

Following 3 to 6 months of bed rest and chemotherapy the average patient with moderately advanced pulmonary tuberculosis will have attained maximal improvement from an x ray standpoint and cultures of sputum and gastric washings will be negative for tubercle bacilli At this point tomograms are made and if the residual lesions are insignificant in size and extent ambulation is increased This is a gradual process requiring at least 3 months before the patient is up for the whole day Another 3 months is allowed before he returns to work Most patients of this type are discharged from the hospital 6 to 8 months after admission and continue drug therapy on an outpatient basis for at least another 6 to 12 months

If tomograms reveal the presence of cavities or other significant lesions the diseased lung tissue is resected In the type of case under consideration surgery is ordinarily performed between 4 and 8 months after admission to the hospital If the post operative course is uneventful ambulation is begun 2 to 4 weeks later and the subsequent course is as outlined above

This example illustrates the usual procedure in the average uncomplicated case Patients with minimal lesions probably require less therapy and in patients with far advanced bilateral disease the situation is often much more complex and time consuming In such cases the sputum often remains positive and new drugs are added before surgery is performed On the average however the period of hospitalization is much shorter than it formerly was For example in many tuberculosis hospitals the average hospital stay is only 8 months as opposed to 20 months formerly Providing facilities for administering chemotherapy on an outpatient basis is an important feature of the program

Treatment of Special Conditions The general principles underlying the treatment of pulmonary tuberculosis have been described above but the management of certain features deserves special consideration

Hemoptysis Pulmonary hemorrhages are not infrequent in patients with pulmonary tuberculosis and represent a dangerous and alarming complication Fortunately closure of the ulcerated blood vessel occurs promptly in most instances Allaying fears of the patient concerning a possible fatal termination of the episode is an important part of the management of hemoptysis The patient is instructed to lie on the affected side to prevent material laden with bacilli from flowing into other parts of the lungs and spreading the disease If the side from which the blood is coming is not known to the physician from previous examination and x rays the patient often can sense it from a peculiar feeling in one side of the chest Although he lies mostly on the affected side for a few minutes every hour the patient should roll onto the other side so that bloody discharges may drain into the trachea and be removed by gentle coughing The time-honored warning against injudicious use of opiates is sound but small doses of codeine may be a valuable aid in preventing spread of the disease by converting a severe intractable cough into one that is mild but effective The patient usually brings up dark clots of blood over a period of several days as the episode subsides In some instances the bleeding continues or recurs and in such cases it may be necessary to institute artificial pneumothorax, which allows the bleeding vessel to contract and usually terminates the hemorrhage If possible pneumothorax should be avoided since collapsing the lung during the acute episode impairs drainage of the retained secretions and the danger of pleural complications is great If artificial pneumothorax is unsuccessful, phrenemphraxis or pneumoperitoneum is occasionally instituted in an attempt to stop the bleeding If bleeding persists transfusions should be given Many drugs such as calcium gluconate atropine ascorbic acid vitamin K, and nitroglycerin have been thought to be effective in isolated cases of hemoptysis but their general use cannot be recommended Fresh exudative lesions which follow hemoptysis respond extremely well to chemotherapy In many instances of course the exudative "spread" is mostly blood which would disappear on rest alone within a few weeks

Spontaneous Pneumothorax and Bronchopleural Fistula Spontaneous pneumothorax is a relatively common occurrence in young adults It usually begins suddenly with a sharp pain in the anterior chest and in the majority of instances is due to the rupture of a subpleural bulla The bulla may be secondary to fibrosis caused by tuberculosis or other infections or it may be congenital The available evidence indicates that only a small percentage of spontaneous pneumothoraxes are tuberculous in origin and therefore bed rest is not prescribed unless a parenchymal focus is demonstrated or tubercle bacilli are recovered (see p 1381)

When tuberculous in origin, spontaneous pneumothorax results from the ulceration of a subpleural caseous focus or the rupture of a tuberculous cavity directly into the pleural space If possible the lung should be reexpanded at once using catheter drainage with controlled suction for this is a much more serious situation than is the rupture of a bulla In this instance the fistula carries large numbers of tubercle bacilli into the pleural cavity causing infection, fluid formation, and the development of empyema. This may be a

however collapse therapy is indicated in only a small percentage of patients with pulmonary tuberculosis *even when cavities are present* The various forms of collapse therapy will be reviewed briefly and the indications for each will be presented

Pneumoperitoneum This is the only form of collapse therapy which is still used widely and in some leading clinics even this method has been virtually abandoned Administration of air into the peritoneal cavity is simple from a technical standpoint and complications are rare Pneumoperitoneum can be maintained for a long period of time and yet can be abandoned at any time The chief indication is extensive exudative disease with bilateral cavitation In such cases pneumoperitoneum may aid in improving the patient s condition to the point where resection of residual cavities and necrotic foci is feasible In patients unable to withstand surgery refills may be continued indefinitely

Artificial Pneumothorax Designed originally for predominantly unilateral disease with cavitation this form of therapy produced brilliant results in carefully selected cases Because of the high incidence of pleural complications however its use has been virtually abandoned

Phrenemphraxis Temporary paralysis of the diaphragm is effected by crushing the phrenic nerve The diaphragm remains elevated and immobile for 6 or 8 months and then gradually resumes its normal function The main disadvantages of phrenemphraxis are gastrointestinal disturbances especially when it is performed on the left side failure of the nerve to regenerate in about 10 per cent of cases and reduction in respiratory reserve This procedure is rarely used at present

Thoracoplasty Until recently the classic indication for thoracoplasty was chronic fibroid disease at or near the apex of one lung with a cavity which could not be closed effectively or safely by other means Now however surgical excision is performed in the great majority of patients who formerly would have undergone thoracoplasty Primary thoracoplasty is now reserved chiefly for patients with an apical cavity in whom resection is not possible and in whom other measures have failed

Resection It is evident from all that has been said above concerning treatment that surgical resection has become an important part of the management of pulmonary tuberculosis The principal indication for resection is the persistence of open cavities and residual necrotic foci with or without positive sputum following several months of rest and chemotherapy In addition to open cavities solid areas with a diameter greater than 4 cm should probably be resected This problem will be considered in greater detail below in relation to viability of the tubercle bacilli

Following prolonged chemotherapy it is relatively simple to remove small wedges of lung tissue and often several can be resected at one time Little functioning pulmonary tissue is sacrificed and these subsegmental resections can be performed on both lungs With more extensive involvement segmental resection lobectomy or pneumonectomy are indicated Except when lobectomy or pneumonectomy are necessary the mortality rate from surgery should be well under 1 per cent

Bronchopleural fistula and empyema are the most serious problems following resection These can be minimized by deferring surgery until endobronchial disease is well controlled Postoperative spread of the disease formerly a major hazard now occurs in less than 2 per cent of resections If a large amount of lung tissue such as a whole lobe is removed overdistention of the remaining lung tissue may be prevented by performing a thoracoplasty The need for thoracoplasty following lobectomy or even pneumonectomy is open to serious question however and it is now customary to perform the procedure only if signs of overdistention appear several weeks after the resection

Viability of Tubercle Bacilli in Resected Lesions When residual necrotic foci are removed following prolonged chemotherapy they often contain large numbers of tubercle bacilli which appear normal on smear but do not grow on culture media and do not cause disease in guinea pigs This phenomenon was also observed prior to the introduction of chemotherapy and is invariably associated with closed lesions Since the organisms appear normal and healthy the possibility has been raised that they are actually viable but have been so altered by the chemical composition of the closed necrotic lesion that they are incapable of multiplying when subjected to the usual tests Hobby has shown that with appropriate technique growth can often be obtained after many months of incubation in special culture media The need for resecting necrotic foci remains unsettled however since the danger from these metabolically inactive organisms probably decreases with the passage of time Control studies which are still in their early stages do not show a higher incidence of relapse in patients with closed lesions who receive prolonged chemotherapy without surgery Except in clinics where these studies are being carried out only the larger residual necrotic foci (those over 3 or 4 cm in diameter) are routinely resected

Correlation of Rest Chemotherapy, and Resection The manner in which various forms of therapy are correlated especially from the standpoint of time relationships can be considered briefly The statements which are made are somewhat tentative

tive measures mentioned above are unnecessary Pain subsides within a few days and the ulcers heal within a few weeks

Chemotherapy exerts a similarly favorable influence in tuberculous tracheobronchitis Tracheobronchial lesions consist of ulcerations or of granulomatous infiltrations which tend to occlude the bronchial lumen as they undergo fibrosis and healing Stenosing bronchial lesions are to be suspected in the presence of wheezing especially when this is localized over one lung or over a single lobe Episodes of pneumonitis occur distal to the stenosis owing to impairment of the normal drainage of secretions and bronchiectasis may appear in the affected lobe Bronchoscopy aids in determining the nature and extent of the tracheobronchial disease and in assessing the efficacy of antimicrobial therapy Old fibrotic cicatricial stenoses are not benefited by chemotherapy and resection is usually necessary

Generalized Miliary Tuberculosis Resulting from the sudden entry of large numbers of tubercle bacilli into the blood stream miliary tuberculosis is characterized by seeding throughout the tissues of small foci of roughly the same age and size The source of the bacilli is probably in most instances a caseous hilar or mediastinal lymph node which erodes into a blood or lymph vessel Caseous foci in other organs such as the kidneys bones adrenals and prostate may also give rise to massive blood stream invasion Tubercle bacilli are carried to every part of the body but some organs such as the pancreas thyroid skeletal muscles brain and stomach show little or no involvement

Miliary tuberculosis occurs most frequently during the period when the primary complex is active the peak is during early childhood The condition is not rare however in adults The onset may be sudden with high fever aching chilliness and prostration or it may be gradual with an initial period of general malaise and weakness Cough is not a striking feature and if present is usually mild and nonproductive The diagnosis often remains obscure until characteristic miliary lesions appear on the roentgenogram which may not be until several weeks following the onset of symptoms In general when there is an acute onset with high fever and marked prostration the lesions are exudative while in patients with a more insidious onset and low fever a productive reaction is predominant The white blood count may vary from agranulocytosis to marked leukocytosis or there may even be a leukemoid reaction Other conditions which may present a clinical and x ray picture similar to that of miliary tuberculosis are the following

Sarcoidosis
Hemosiderosis
Periarteritis nodosa
Tuberous sclerosis
Lymphangitic carcinomatosis
Silicosis (first and second stage)
Chemical bronchiolitis
Histoplasmosis
Coccidioidomycosis
Bagassosis
Eosinophilic pneumonia (Loeffler s syndrome)
Beryllıosis
Pulmonary adenomatosis
Varicella pneumonitis

Because the lesions are interstitial the recovery of tubercle bacilli is often delayed for many weeks Tubercle bacilli can often be cultured from the bone marrow and sometimes the blood

Heretofore miliary tuberculosis has been a highly fatal condition with death characteristically occurring 6 to 10 weeks following the onset This situation has been altered dramatically by chemotherapy Fever and toxemia usually subside within a few days and within a few weeks the pulmonary lesions begin to show regression In the early days of streptomycin therapy when treatment was continued for only 2 or 3 months over half the cases relapsed and died With prolonged combined chemotherapy recovery occurs in more than 85 per cent of cases and relapses are rare This is one of the forms of tuberculosis in which all three of the antimicrobial agents—isoniazid streptomycin and PAS—are administered simultaneously One gram of streptomycin is injected every day for the first 4 months then twice weekly The daily dosages of isoniazid and PAS are 0 3 to 0 6 Gm and 12 0 Gm respectively Treatment is continued for 2 years

Tuberculous meningitis often occurs during the course of miliary tuberculosis even when the patient is receiving streptomycin therapy Since the addition of ioniazid to the chemotherapeutic regimen however this complication has rarely been observed It is therefore less important to perform frequent lumbar punctures in patients with miliary tuberculosis than it was a few years ago

Subacute and Chronic Hematogenous Tuberculosis Instead of a single massive invasion of the blood stream smaller numbers of tubercle bacilli may escape intermittently into the circulation and give rise to a variety of clinical manifestations Among the more common manifestations are low grade fever local or generalized lymphadenopathy effusions into the pleural and peritoneal cavities splenomegaly and destructive lesions of the bones kidneys skin and eyes

The protean manifestations and bizarre clinical picture caused by subacute and chronic forms of hematogenous tuberculosis provide diagnostic puzzles which often can be solved only by cultures of secretions or discharges or by biopsy of the affected tissues It should be borne in mind that hematogenous foci may remain latent in various organs for many years

simple tuberculous empyema or other organisms such as streptococci and staphylococci may pass through the fistulous opening to form a mixed infection empyema An open bronchopleural fistula with empyema is a dangerous situation the empyema fluid may drain slowly through the fistula into the bronchi and lungs causing widespread dissemination of the disease or if the fistula suddenly enlarges several hundred milliliters of pus may flood into the bronchial tree causing the patient to drown in his own secretions A patent bronchopleural fistula should be suspected when the patient coughs up material similar to pus aspirated from the chest and may be proved by injecting methylene blue into the empyema cavity and subsequently observing the dye in the sputum Once diagnosed a bronchopleural fistula is an indication for surgical drainage because of the dangers mentioned above and because of the failure of mixed infection empyemas to respond to aspiration and irrigations

Tuberculous Empyema This condition is considered separately for its management differs somewhat from that of bronchopleural fistula with mixed infection empyema Pure tuberculous empyema may appear spontaneously or as a complication of artificial pneumothorax or surgical resection There is a tendency to regard all effusions as empyemas if tubercle bacilli can be recovered This is misleading for with clear effusions the prognosis is much more favorable than in true empyemas in which the fluid is thick purulent and swarming with bacilli With chemotherapy aspiration and irrigation and instillation of streptokinase and streptodornase considerable improvement may occur but the empyema is usually not obliterated The procedure of choice at the present time is to excise the entire empyema cavity proceeding extrapleurally as much as possible Diseased lung tissue is resected at the same time To obliterate the space and prevent a recurrence of the empyema a thoracoplasty is usually performed An unroofing procedure of the Schede type which is dangerous and deforming is rarely necessary

Fibrinous and Serofibrinous Pleurisy Pleural involvement occurs in most cases of pulmonary tuberculosis One indication of this is the high incidence of pleural adhesions in patients receiving artificial pneumothorax The adhesions result from localized areas of fibrinous pleurisy overlying peripherally located parenchymal foci and the apposition of the two pleural surfaces aids in localization of the process With fibrinous pleurisy symptoms may be absent or there may be sharp pleuritic pain and a friction rub may be detectable The course of fibrinous pleurisy is usually mild and except for local palliative measures attention should be directed at the underlying parenchymal disease

Five to ten per cent of patients with pulmonary tuberculosis develop serofibrinous pleurisy which is discussed on p 939 Care must be taken to exclude other causes of serous effusions such as pneumonia a careful analysis of clinical signs and symptoms prior to the onset of the effusion is usually adequate to make this differential

Fluid is aspirated initially for diagnosis After removal of most of the effusion 100 ml of air may be injected into the pleural space allowing the remainder of the fluid to fall to the base so that the pulmonary parenchyma can be visualized clearly on the x ray Opinion is divided as to whether repeated aspirations should be performed if the fluid persists and increases in amount after the first tap The author feels that fluid should be removed repeatedly to prevent incarceration of the lung The fluid usually does not reappear after several thoracenteses have been performed and there is a minimal degree of mediastinal shift and pleural thickening It is generally agreed that artificial pneumothorax is contraindicated because the presence of air impedes healing and the lung often does not reexpand after being collapsed for a prolonged period in the presence of fluid

In addition to aspirations the treatment is that prescribed for an active case of minimal tuberculosis namely rest and chemotherapy Isoniazid alone is probably adequate in such cases but most authorities prefer to administer PAS in addition

EXTRAPULMONARY TUBERCULOSIS

Laryngeal and Tracheobronchial Tuberculosis Tuberculous laryngitis usually occurs in patients with advanced pulmonary tuberculosis the infection resulting from the continual passage of bacilliferous sputum over the vocal cords and accessory structures which are irritated by the chronic cough Rarely laryngeal lesions are seen in patients with little or no active pulmonary tuberculosis and the infection then is presumably hematogenous or lymphogenous in origin Hoarseness and a dry sensation in the throat are the common symptoms the diagnosis can be confirmed by direct or indirect laryngoscopy and a biopsy The posterior part of the larynx and vocal cords are first involved and later there are deep extensive ulcerations of the laryngeal cartilages including the epiglottis With the latter there is severe pain on swallowing which interferes with eating Heretofore treatment consisted of complete voice rest cauterization of granulations or deep ulcerations anesthetic sprays to relieve pain and antibiotics to reduce secondary infection With chemotherapy however the condition usually responds so well that most of the pallia

tissues of the pharynx or tonsils has been virtually eliminated but cervical adenitis of lymphohematogenous origin is still observed in both adults and children The swelling usually begins insidiously and may involve one or many nodes The lymph nodes tend to be matted but this is not a reliable diagnostic feature The skin often perforates at one or more sites permitting the drainage of thick greenish yellow pus The treatment of tuberculous cervical adenitis consists of rest and chemotherapy with surgical removal of the residual nodes after several months if they are still enlarged Results with isoniazid and PAS or with isoniazid alone have been so good that surgery usually is unnecessary

Gastrointestinal Tuberculosis Tuberculous ulcers occur occasionally on the tongue lip pharynx and tonsils The diagnosis is made by curetting or excising a small portion of the involved tissue and preparing microscopic sections These lesions respond very well to chemotherapy

Tuberculosis of the esophagus and stomach is rare The *intestine* however especially the lower ileum and cecum is frequently involved in patients with advanced pulmonary tuberculosis as a result of swallowing bacilli The symptoms of ileocecal tuberculosis are variable consisting chiefly of intermittent indigestion colicky pain constipation and diarrhea The appearance of any unusual gastrointestinal complaints should arouse suspicion especially in patients with far advanced pulmonary involvement A moderate anemia is common and should direct attention to the intestinal tract whenever present in patients with pulmonary tuberculosis X ray studies of the ileocecal region provide valuable confirmatory evidence of spasticity and hypermotility The treatment is directed at both the pulmonary lesions and the ulcers in the bowel For the latter a low residue bland diet diminishes irritation of the bowel wall and opium derivatives or bismuth compounds are given to relieve the pain and diarrhea Chemotherapy which is prescribed for the pulmonary disease usually brings about healing of the intestinal lesions In some cases an excessive amount of irritation is caused by PAS and it is wise in most instances therefore to administer streptomycin and isoniazid

Tuberculous Peritonitis This condition results from extension of local lesions in the intestine lymph nodes or genital tract or it may be caused by hematogenous spread from other parts of the body Serofibrinous peritonitis usually has an insidious onset with mild constitutional symptoms and vague intestinal complaints As with serofibrinous pleurisy however the onset may in some cases be acute with high fever severe abdominal pain and marked prostration Fluid often appears especially in the more toxic cases and may require repeated aspirations to relieve distention and discomfort Treatment consists of rest and chemotherapy using the same regimens as for pulmonary tuberculosis As healing occurs thick adhesions may form matting the intestines and omentum together interfering with normal peristalsis and causing stenosis of various portions of the bowel Unless the adhesive process is localized and surgically resectable as it sometimes is in the region of the cecum the treatment is symptomatic and palliative Fortunately this complication is uncommon

Genitourinary Tuberculosis ***Tuberculosis of the Kidney*** In most instances this occurs by hematogenous dissemination from foci in the lungs or lymph nodes occasionally infection may come from the genital tract Small foci may remain latent in the kidneys for long periods before causing destructive lesions many patients with renal tuberculosis show no evidence of active pulmonary disease As the ulcerative lesions in the kidney enlarge tubercle bacilli escape into the urinary tract and often infect the ureters and bladder Dysuria and hematuria are the main symptoms but cases of renal tuberculosis are not infrequently diagnosed before symptoms appear Blood and pus are found in the urine and tubercle bacilli are recovered from the centrifuged sediment by culture or guinea pig inoculation Intravenous and retrograde pyelograms often show characteristic renal ulcerations retrograde studies are particularly helpful in determining whether the involvement is bilateral Lattimer has shown that chemotherapy of renal tuberculosis is so effective that surgery is now rarely necessary Triple drug therapy (isoniazid streptomycin and PAS) was used in his studies and was continued for 1 to 2 years It is now felt that damaged kidney tissue should be removed only if there is a relapse after prolonged drug therapy

Genital Tuberculosis Genital tuberculosis is almost invariably hematogenous in origin and in the male involves the prostate seminal vesicles epididymides and occasionally the testes Infection of the genital tract may in occasional instances be secondary to renal tuberculosis Clinically involvement of the epididymis is diagnosed most frequently although pathologic examinations reveal a higher incidence of tuberculosis of the prostate and seminal vesicles Tuberculous epididymitis often begins insidiously with a gradual development of nodular infiltrations which are moderately tender The onset is sometimes acute with sudden swelling redness and marked tenderness of the epididymis and surrounding structures Rest and chemotherapy are indicated and the epididymis and seminal vesicles are removed only if there are large residual masses of inflammatory tissue

Genital tuberculosis in the female involves the fallopian tubes more frequently than the other

Tuberculous Meningitis As in miliary tuberculosis tuberculous meningitis is more common during early childhood than at any other age period The percentage of adults infected with the tubercle bacillus who die of tuberculous meningitis is relatively small The evidence of Rich indicates that the meninges are infected by direct extension from an adjacent focus In miliary tuberculosis Rich showed that meningitis results not from the direct escape of large numbers of bacilli into the meninges from the blood stream but from miliary meningeal tubercles which gradually enlarge to produce direct extension or that it arises from older dormant foci which became reactivated and extend into the meningeal spaces Pathologically the reaction consists of tubercles edema and congestion and a fibrinous exudate most marked over the base of the brain Various cranial nerves are commonly affected

Tuberculous meningitis may appear in individuals who previously were apparently entirely well The symptoms of miliary tuberculosis usually precede those of tuberculous meningitis by several weeks when the two occur together The early symptoms of tuberculous meningitis are headache restlessness and irritability and on examination typical signs of meningeal irritation are usually elicited The spinal fluid pressure is elevated and there is an increase in protein and cells most of which are mononuclear The chlorides and sugar are depressed moderately in some cases markedly in others On standing a pellicle usually forms Smears of the centrifuged sediment or pellicle may reveal tubercle bacilli but in the majority of cases they do not Repeated cultures and guinea pig inoculations usually are necessary to recover the causative organism

Until streptomycin became available there was no urgency about establishing the diagnosis of tuberculous meningitis treatment was purely supportive and the outcome almost always fatal Now however treatment must be started in many cases before the organisms are recovered Early differentiation between tuberculous meningitis and meningitis due to other agents chiefly fungi and viruses is at times impossible in such cases chemotherapy should be administered if tuberculosis seems the probable cause on the basis of a positive tuberculin test marked depression of the spinal fluid sugar and chloride and the general clinical picture

The treatment of tuberculous meningitis is identical with that outlined above for miliary tuberculosis except that streptomycin should probably be given in daily doses of 2 Gm rather than 1 Gm for the first 4 months Intrathecal administration of streptomycin has been largely abandoned greatly simplifying therapy Intrathecal administration of tuberculin has given dramatic results in some cases but cannot be recommended until the benefits and dangers are more clearly defined Corticosteroids produce a dramatic decrease in fever and toxicity and may diminish the formation of exudate about the base of the brain Their use is probably indicated in most if not all cases these hormones can usually be discontinued by the end of the first month

With the availability of isoniazid the cure rate is in the neighborhood of 80 to 90 per cent in many clinics and poor results occur mostly in patients who are treated late in the course of the disease Many patients make a complete clinical recovery without mental impairment or neurologic defects

Tuberculosis of Lymph Nodes Tuberculosis of hilar and mediastinal nodes which is the commonest form of tuberculous lymphadenitis has its inception during the primary infection when tubercle bacilli escape freely from the initial pulmonary lesion Children with a primary infection may have massive lymph node involvement with few constitutional manifestations The symptoms in such cases are due chiefly to pressure on surrounding structures and consist of wheezing dyspnea and hacking cough In addition compression of a bronchus may cause collapse of one or more lobes with pneumonitis caused by other bacteria distal to the site of narrowing Except when there is perforation into a bronchus or when death results from progressive tuberculosis the involved nodes show a marked tendency to heal and become calcified Even with apparent healing however viable tubercle bacilli may remain in the nodes for long periods Aside from rest and chemotherapy x ray and tuberculin therapy are sometimes recommended but are of questionable value and are potentially dangerous because excessive doses may aggravate tissue necrosis Chemotherapy was at first unimpressive probably because of poor penetration of streptomycin into the large caseous nodes Isoniazid is effective however not only in promoting healing of the mediastinal nodes but in preventing spread to other organs Isoniazid is often used alone in milder cases in children but with extensive involvement streptomycin or PAS should be added Calcified nodes occasionally perforate into a bronchus many years after the primary complex apparently has become arrested This condition known as *broncholithiasis* is characterized by pneumonitis hemoptysis and expectoration of small bits of calcified material

Cervical adenitis or scrofula has become relatively uncommon in the United States in the past 50 years as a result of the elimination of tuberculous cattle and the widespread pasteurization of milk Direct infection by tubercle bacilli through the

marked decrease in the number of domiciliary cases Further advances in therapy can be expected and it is probable that it will eventually be possible to arrest the disease permanently in most patients

One deterrent to this optimistic outlook is the fact that socioeconomic factors are becoming increasingly important Most patients with tuberculosis are among the lower income groups and are individuals who have adjusted themselves poorly to the stresses and strains of modern society The aid of social service workers occupational therapists and psychiatrists is therefore of the greatest importance in the over all plan of rehabilitation

PREVENTION AND ERADICATION OF TUBERCULOSIS

The remarkable decline in the mortality rate from tuberculosis during the first two decades of the twentieth century led a number of careful students of the problem to predict the virtual eradication of the disease by 1950 or earlier The fallacy in the prediction lay in the assumption that the number of individuals harboring active lesions would fall to the point that the disease would cease to propagate itself This has not occurred as pointed out in the section on Prevalence and Incidence the decline in the mortality rate is probably due chiefly to improved living conditions and other factors which tend to increase resistance but the incidence of infection of the population as a whole remains relatively high This means that a large number of individuals with active disease are not hospitalized and remain at large to infect the general populace Evidence indicating the occurrence of such "carriers is provided by the fact that no apparent source of contact can be found for most adults with pulmonary tuberculosis Autopsy studies further indicate that undiagnosed cases of active tuberculosis are common in older people especially males

Preventive measures in addition to the improvement in living conditions which have contributed greatly to the advances accompanying the antituberculosis campaign are earlier diagnosis and treatment isolation of active cases better hospital facilities programs for the rehabilitation of patients with arrested disease to prevent relapse examination of close contacts of tuberculous patients large scale x ray surveys elimination of tuberculous cattle and pasteurization of milk Much has been accomplished but in almost every one of the above categories present efforts and results fall far short of what is desired

BCG (Bacillus Calmette Guerin) an attenuated bovine tubercle bacillus has been used widely abroad for vaccination against tuberculosis Controlled studies of its efficacy are difficult to conduct but the experiments which have been made seem to provide some evidence of its value Protection is by no means complete but a sufficient degree of acquired resistance is conferred to warrant consideration of its use among tuberculin negative groups in which exposure to tuberculosis is especially likely to occur Examples are tuberculin negative nurses medical students and individuals living under poor economic conditions in overcrowded urban areas In many medical and nursing schools the incidence of tuberculosis is so low that the use of BCG has been abandoned

organs and the lesions are more often unilateral than bilateral Less commonly the ovaries and uterus may be the site of destructive lesions the cervix vagina and labia are rarely affected Vague *irregular lower abdominal pain may be the only* symptom of tuberculous salpingitis and an adnexal mass may be found on pelvic examination If the uterus is involved tubercle bacilli may be present in the vaginal discharge or tuberculous tissue may be removed by curettage The menses may be normal but in advanced cases are usually scanty or absent Tuberculous salpingitis is potentially dangerous because it may cause diffuse peritonitis Again the trend is toward prolonged chemotherapy with surgery only if there are large residual masses

Pericarditis The pericardium can become infected in tuberculosis by discharge of the contents of a caseous mediastinal lymph node into this space by hematogenous dissemination (involvement of serous surfaces by this means is relatively rare) or by direct extension from nearby pleuropulmonary lesions The inflammatory process in the pericardium varies from a serofibrinous reaction containing relatively few bacilli (presumably a response *to sudden discharge of tuberculoprotein onto a* sensitized serous surface similar to that in pleurisy with effusion) to extensive fibrocaseous lesions containing myriads of acid fast organisms

The clinical picture produced by tuberculous infection of the pericardium is extremely variable The sudden onset of substernal pain and fever with accompanying signs such as a to and fro friction rub Ewart s sign etc (see p 1279) in a patient known to have had tuberculosis makes the diagnosis relatively easy However the disease may be entirely asymptomatic attention being drawn to it by the finding of enlargement of the cardiac shadow in a routine x ray of the chest Again because of epicardial and myocardial involvement or tamponade patients may be thought to have congestive heart failure of many etiologies Low grade fever vague complaints of discomfort in the chest and mild weight loss may be the only complaints The finding of pericardial adhesions in many tuberculous patients at autopsy suggests that many instances of minimal pericardial tuberculosis may spontaneously subside and become inactive While occasional patients may accumulate large amounts of fluid in the pericardium sometimes bloody and require repeated aspirations to avoid serious circulatory difficulties this is not usual In such cases there is often simultaneous involvement of one or both pleural spaces leading to confusion with such diseases as systemic lupus erythematosus pyogenic infections and benign idiopathic" pericarditis Occasional patients with tuberculosis of the pericardium run an intermittent course experiencing several bouts of pain and fever with friction rubs reaccumulation of fluid etc

Tuberculosis of the pericardium is the commonest cause of constrictive pericarditis The fibrosis and *calcification that accompany the healing process in* this infection can lead to encasement of the heart in an unyielding tunic of dense scar with serious effects upon the circulation (ee p 1282)

Diagnosis by demonstration of tubercle bacilli in smears or cultures of aspirated fluid is often difficult and in cases of doubtful etiology pericardial biopsy is becoming an increasingly feasible and useful procedure The institution of chemotherapy of the type recommended for pulmonary tuberculosis before operation makes spread of infection unlikely It is not uncommon to find a surprising amount of pericardial scar when operation for biopsy is carried out and in such instances many feel that pericardiectomy can and should be done The final place of early surgical treatment in tuberculous pericarditis remains to be determined It is clear however that in some cases where infection is arrested or eradicated by chemotherapy sufficient mechanical difficulty can remain to warrant *excision of the thickened membrane* The duration of drug treatment should be at least a year and indications for rest proper diet etc differ in no way from those in other forms of tuberculosis

Skeletal Tuberculosis Bone and joint tuberculosis is usually hematogenous in origin and is most likely to occur in young children In adults the incidence is higher in males and it is more frequent in Negroes than in whites With joint involvement diagnosis depends on study of aspirated fluid or pus and on surgical biopsy Destructive bone changes visible on roentgenograms often occur late In over half the cases there is active pulmonary tuberculosis and a presumptive diagnosis can often be made on this basis

Chemotherapy if started early often results in a complete return of function of the involved joints With marked bone destruction surgical immobilization (arthodesis) is usually necessary but this is carried out only after a period of drug therapy Triple drug regimens similar to those used for genitourinary tuberculosis should be employed Details of orthopedic procedures are beyond the scope of this presentation Close cooperation between the internist and orthopedist is obviously desirable

PROGNOSIS

The outlook for the great majority of patients with tuberculosis has been vastly improved by the availability of effective chemotherapeutic agents and advances in surgical management The case fatality rate is falling rapidly and there has been a

contacts never exhibiting clinical disease may play a role in transmission If so the incubation period may not be so long as currently suspected

Pathologic Anatomy The lesions may be classified according to their microscopic appearance This leads to the recognition of four principal types (1) the lepromatous (2) the tuberculoid (3) the dimorphous and (4) the indeterminate

In the *lepromatous type* bacilli are numerous they multiply intracellularly there is little cellular response and little evidence of resistance to the disease The cutaneous lesions are usually numerous are symmetric in distribution and take the form of nodules papules macules and diffuse infiltrations Most characteristic is the appearance of the leproma or nodule It is distinguished by the lepra cell" a large macrophage containing numerous bacilli and fat droplets In large accumulations bacilli form globi and rosettes

The *tuberculoid* lesions are observed in cutaneous leprids and the affected nerves The leprids are often macules and are usually asymmetric in distribution Bacilli are few or absent and epithelioid cells giant cells lymphocytes and plasma cells are present often in the form of tubercles

The *dimorphous* lesion which is uncommon and presumably represents a transient state has microscopic features of both the lepromatous and tuberculoid forms

The *indeterminate type* of lesion contains few bacilli and shows a slight cellular reaction which is limited to the perivascular and perineural areas The gross lesions in the skin and nerves are not characteristic or advanced enough to permit classification with the two principal clinical types

Clinical Classification A combined clinicopathologic classification is recommended since it makes more direct clinical immunologic bacteriologic and epidemiologic correlations possible That is regardless of the sites involved the lepromatous type is characterized by a relatively rapid course a negative lepromin reaction and lesions containing many bacilli and because of this is an "open or dangerous type for the community The tuberculoid type has a more chronic course shows more resistance to the disease has a positive lepromin reaction has few bacilli in the lesions and is therefore a closed type and less of a community hazard The indeterminate type is viewed as a transitional form The lepromin reaction in this type has prognostic significance since many cases with negative reactions develop into the lepromatous type and those with positive reactions into the tuberculoid type The dimorphous type is a macular lesion not representative of a particular clinical group

The distribution of types varies in different geographic areas The tuberculoid type is often preponderant in areas known to have had leprosy for long periods and where control has shown some degree of effectiveness the lepromatous type may predominate in newly involved areas and those in which control has been less effective

Clinical Course The onset is often unheralded and difficult to date The incubation period averages about 3 to 5 years Claims of very long incubation periods must be scrutinized since minor lesions are likely to remain unrecognized for long periods

Initial skin lesions of the lepromatous type usually are found on the extensor surfaces the forehead cheeks and ears Their development may be so gradual that the changes may be noted by others before the patient himself is aware of them

Early signs of mucosal involvement in the upper respiratory and intestinal tracts may be evidenced by nasal discharge dysphagia and hoarseness and dyspnea due to laryngitis

The patient with the tuberculoid type is more likely to be aware of the disease early The initial lesions usually take the form of hypopigmented or erythematous anesthetic macules Subjective manifestations due to neural involvement consist of numbness tingling and formication and the skin may show burns or other lesions which the patient states are painless

The progressing cutaneous leprids of tuberculoid leprosy enlarge and clear centrally The central area is anhidrotic and anesthetic to light touch pain, and thermal stimuli The nerves later are thickened and tender if the disease progresses Before nerve destruction and atrophy occur pain of a neuritic type may be prominent Late stages are characterized by resorption of the small distal bones of the hands and feet and painless ulcers of the extremities

Although more marked in lepromatous leprosy generalized lymph node enlargement is common in all types of leprosy

The lepromin skin test is primarily of prognostic value The test material is prepared from lepromatous nodules Those with tuberculoid leprosy generally show positive reactions and lepromatous cases negative reactions A satisfactory therapeutic response is shown by the transformation of a negative to a positive reaction in the lepromatous type Those patients with the indeterminate type of lesion who have positive lepromin tests are likely to develop tuberculoid lesions if the disease progresses and those who have negative lepromin reactions lepromatous lesions

Recent studies have defined better the relationship between tuberculosis and leprosy The guinea pig normally lepromin negative becomes lepromin positive after BCG (Bacillus Calmette Guerin) administration Patients who have remained lepromin negative after sulfone treatment may become lepromin positive following BCG ad

142 LEPROSY (Hansen's Disease)

Gustave J Dammin

Definition Leprosy is a specific infectious disease of man caused by the *Mycobacterium leprae* It is usually characterized by a long incubation period a long course with exacerbations and remissions and involvement primarily of the skin and mucous membranes and/or the peripheral nervous system The major forms of the disease are the polar forms the lepromatous and the tuberculoid in addition there are dimorphous and indeterminate forms

History Whether leprosy as it is understood today was described in the ancient records has been questioned (Lendrum) In Europe leprosy appeared first in Greece in the fourth century B C probably having been introduced from the East It spread northward and westward and had affected most of Europe by the end of the tenth century A D Leprosy was prevalent in Europe until the fourteenth century and then began slowly to decline

As leprosy was declining in Europe it was being spread to the Western Hemisphere by the slave traders and the discoverers from Portugal and Spain In the United States leprosy appeared first in Louisiana in 1758 presumably spread from the West Indies Additional foci were established from other sources in Minnesota from Norway in California and Hawaii from China and India

Etiology *Mycobacterium leprae* described by Hansen in 1874 is accepted as the causal agent in human leprosy even though the organism has not been cultivated and attempts to transmit leprosy to animals or man have not been successful (Hansen)

Mycobacterium leprae is a pleomorphic acid fast non spore forming gram positive bacillus Lepra bacilli differ from tubercle bacilli in that they (1) are found in tremendous numbers in lesions (lepromatous) in the form of packets palisades and globular masses (globi) both intra and extracellularly (2) decolorize more readily (3) may be stained with the stronger bacterial stains (4) cannot be cultivated and do not produce disease in animals following inoculation

Epidemiology and Pathogenesis The exact mode of transmission is not known A history of prolonged direct contact usually beginning in childhood is common Leprosy may not manifest itself clinically until 1 to 5 years after the period of exposure and appears most often during the third decade of life Resistance to leprosy appears to increase with age

Leprosy is not transmitted to the offspring and it is well known that infants born of leprous parents if removed and reared in an environment permitting no contact do not develop the disease Those not separated are likely to develop leprosy in early life even when separated at six months of age 50 per cent of the children had clinical manifestations by the age of five years

Of interest are cases recognized as accidental inoculation leprosy One report concerns two marines who were tattooed successively by the same man in Melbourne Australia on the same day in June 1943 Both developed maculoanesthetic leprosy in the tattoos about 2½ years later (Porritt and Olsen)

Lepra bacilli leave the body by many routes In lepromatous leprosy they may escape in the secretions and excretions and through any interruption in the involved skin and mucous membranes The route by which they enter a new host is not known but it is believed that infection occurs by way of the skin and mucous membranes following direct contact

Once in the body the bacilli are probably spread by way of the lymphatics and blood stream and by autoinoculation Localization occurs primarily in the skin and/or nerves and in advanced cases of lepromatous leprosy bacilli are found in many of the viscera Bacillemia occurs more commonly in the lepromatous type

The problem of the carrier state is important and only recently under study It appears possible that

3 to 4 years and some approximately 20 per cent of all clinical cases will show no recognizable improvement

The thiosemicarbazones are *not so effective* as DDS but are occasionally useful as alternative agents The response to isoniazid has been poor in most cases ACTH and cortisone have been found to produce desirable temporary effects but unfortunately have been followed by aggravation of neural and cutaneous lesions Their use is justified *in treatment of the drug fever induced by sulfones* In leprous ophthalmitis cortisone applied locally is advised (Lowe)

Prognosis This is dependent upon the type of leprosy the stage in which treatment is begun and the general health of the patient The occurrence of temporary and occasionally permanent spontaneous disease arrest must be kept in mind The tuberculoid type has a relatively better expectancy although disability is common and the prognosis is relatively better in so far as disease arrest is concerned The lepromatous type has the *poorer outlook With the hope which the sulfone* derivatives hold it should become easier to induce patients to seek treatment earlier Generally pneumonia and tuberculosis are common causes of death In the United States over one third of the cases die with renal insufficiency due to amyloidosis The average duration of life after diagnosis is 20 years and the average age at death is fifty nine years

Control Segregation and early treatment of patients particularly those with the lepromatous type are essential *A program of control should be directed toward encouraging voluntary admission to* a leprosarium The harm the patient may do to himself and his immediate contacts by delaying treatment and the hopefulness with which treatment can now be regarded should be emphasized *Mention has been made of the enlarging role which* mass BCG vaccination has been given in control Efforts to identify and define the carrier state should be intensified and the efficacy of the sulfones in controlling the carrier determined Cultivation of a more objective and less emotional public attitude toward the disease is fundamental to any control program

ministration In some instances clinical improvement has accompanied this change The place of BCG in the treatment of leprosy is yet to be defined but its contribution to control has been accepted in many countries and particularly where tuberculosis is common BCG vaccination in children results in most instances in positive early or Fernandez reactions and late or Mitsuda reactions

The histamine test may be of assistance when the skin lesions are atypical or the neurologic examination cannot be satisfactorily performed The normal cutaneous response to a needle prick through a drop of 1 1 000 histamine consists of a wheal with surrounding erythema When there is impairment of neural function in leprosy only the wheal and no erythematous halo appears

The pilocarpine test showing impairment of the sweating response to intradermally injected pilocarpine is helpful in identification of the leprid

Laboratory Diagnosis Although clinical findings may be sufficient for diagnosis demonstration of the bacilli or the histologic lesion is desirable for confirmation or to observe response to therapy In searching for bacilli in a suspected lepromatous case in which the skin lesions are not distinctive the ear lobule should be examined The lobule is held firmly enough to cause blanching A small incision is made with a sharp scalpel and the material which can be scraped from the edges is spread on a slide Stained by the Ziehl Neelsen or fuchsin method a positive lesion will show numerous acid fast bacilli In suspected tuberculoid leprosy a biopsy is usually necessary

The erythrocyte sedimentation rate is elevated in all types of leprosy but is most increased in the lepromatous type Serologic tests for syphilis performed with the beef heart antigens may be positive in 10 to 40 per cent of cases of leprosy whereas with cardiolipin antigens only 1 to 2 per cent may be positive TPI (*Treponema pallidum* immobilization) tests have been negative in most cases of leprosy unless syphilis also was suspected The beta globulin C reactive protein is present in most cases of active leprosy and absent in most cases of arrested leprosy (Rabson)

Differential Diagnosis In nonendemic areas leprosy is seldom diagnosed early Once leprosy is suspected clinical and laboratory procedures are usually successful in establishing the presence or absence of the disease It must be differentiated from syphilis superficial fungous infections lupus vulgaris lupus erythematosus vitiligo dermal leishmaniasis yaws seborrheic dermatitis psoriasis Boeck s sarcoid rheumatoid arthritis nonspecific neuritis syringomyelia and neurofibromatosis Differentiation from syphilis may be difficult because of clinical similarity and the frequent appearance of positive serologic tests for syphilis in leprosy Important procedures in differential diagnosis are (1) the examination of cutaneous and mucosal lesions for *M leprae* (2) study of skin sensation and reaction to histamine and pilocarpine and (3) examination of the peripheral nerves for thickening and tenderness

Treatment Several considerations must be heeded in evaluating the efficacy of therapy Firstly leprosy is an intermittently progressive chronic disease during which temporary and even permanent spontaneous arrest can occur Secondly the patient seeks treatment during and toward the end of an exacerbation which may naturally be followed by a remission of variable duration Thirdly the initial appearance of an exacerbation may be precipitated by a more or less self limited disease—e g malaria or dysentery—or by an unfavorable nutritional and hygienic state which when corrected may be followed by a remission Clinical and laboratory observation over a period of years is therefore necessary for proper evaluation of therapy

The general therapeutic regimen should resemble that for tuberculosis since much can be accomplished by good diet and regulated rest and exercise Chaulmoogra (hydnocarpus) oil was long used in Asia in the treatment of leprosy but only during the latter part of the nineteenth century was it introduced into Western medicine The Cairo Congress in 1938 regarded chaulmoogra oil and its esters as the most efficacious drugs for the treatment of leprosy Although many cases appeared to be benefited this opinion was not concurred in generally

The sulfone Promin was first used for the treatment of leprosy in 1941 at the Carville National Leprosarium

More recent years have seen the emergence of the sulfones as the most efficacious drugs in the treatment of leprosy Most success has been obtained with the parent sulfone 4 4 diaminodiphenylsulfone (DDS) It is rapidly absorbed after oral administration and slowly excreted cumulative effects therefore occurring when large doses are given Initially 100 mg is given orally twice a week and the dose increased by the same amount each week until the dose of 400 mg twice a week is reached This amount is continued and the patient is observed for toxic effects such as hemolytic anemia hepatitis drug fever dermatitis and psychosis Muir has reported that vitamin B_1 increases the tolerance for DDS

The response to therapy is estimated by periodic bacteriologic examinations and objective clinical studies Early cases and those with low bacteriologic indices can be expected to show improvement after about 1 year of treatment others may require

the urinary tract) and special features of the tissue reaction produced by some bacterial species make *it possible to recognize* infection by them with considerable accuracy The *staphylococci* produce rapid necrosis and early suppuration with large amounts of creamy yellow pus (see p 840) Group A beta hemolytic streptococcal infections (p 849) tend *to spread rapidly through tissues causing intense* inflammatory edema and striking erythema but relatively little necrosis and thin serumlike exudates anaerobic streptococci (p 869) and members of the *Bacteroides* group (p 881) produce necrosis and profuse brownish foul smelling pus *Pseudomonas* infections (p 880) are often rather indolent and their thick bluish green exudate is familiar to most clinicians *the pneumococcus* (p 833) stimulates the production of viscid greenish pus containing large plaques of fibrin and denatured protein

The causative agents of many other diseases are *capable of producing localized infection in tissues* that are not usually involved in the specific "clinical entities ascribed to them Examples include the typhoid bacillus *Corynebacterium diphtheriae* (cutaneous ulcers) *Brucella Pasteurella tularensis* and *many others*

The identification of the infecting organism or organisms is an important procedure in the choice of local or *systemic chemotherapy and should not* be neglected However when one is dealing with infection in an area where exposure to the micro flora of the body is constant (sputum paranasal sinusitis cutaneous ulcers) it is unlikely that cultures will ever *become sterile* and the interpretation of the findings in serial cultures during therapy must be tempered by this realization

Pathogenesis Factors predisposing to the initiation and persistence of infection in a tissue include trauma *obstruction of normal* drainage (*sweat* glands biliary tract bronchial tree urinary tract) ischemia *(infarction gangrene) chemical irritants* (gastric contents bile intramuscularly injected drugs) hematoma formation accumulation of fluid (lymphatic obstruction *cardiac edema*) *foreign* bodies (bullets splinters sutures) and others such as the occurrence of turbulence in the vascular system (see Bacterial Endocarditis p 971)

Infection in soft tissue usually begins as a *cellulitis* a diffuse acute inflammation with hyperemia edema and leukocytic infiltration but little or no necrosis and suppuration With some organisms this is followed by necrosis liquefaction accumulation of leukocytes and debris suppuration loculation and walling off of the pus and formation of one or more *abscesses* Abscess formation is particularly *prone to follow* infection in a preexisting circumscribed space or cavity examples being the fallopian tubes lung cysts and pilonidal sinuses

Ureteral obstruction in the presence of pyelonephritis is sometimes followed by accumulation of large quantities of thick pus in the renal pelvis a *pyonephrosis*

The local spread *of infection generally follows* the path of least resistance along fascial planes proper surgical treatment is based upon a knowl*edge of these routes which will be described for* specific infections later in this chapter Lymphatic spread can lead to lymphangitis lymphadenitis or if the regional nodes suppurate to the formation of a *bubo* Involvement of local venules or large veins can lead *to infective thrombophlebitis with* resulting bacteremia septic embolization and systemic dissemination of infection Staphylococci streptococci and *Bacteroides* are notorious for the frequency with which they produce vascular lesions of this type

Depending upon the infecting organism and the anatomy of the affected region a small abscess may *subside completely there may be gradual encapsul*ation of the accumulated pus and persistence of the focus in a chronic or quiescent state or the lesion may point and rupture into adjacent tissues or to the outside surface of the body as usually hap*pens with furuncles and occasionally with pleural* abscess (*empyema necessitatis*) Spontaneous drainage of the pus to the outside ordinarily leads to subsidence and healing of a superficially situated suppurative focus However if the abscess is deeply situated and *well encapsulated there is often per*sistence of a fistulous tract and the formation of a chronic draining sinus *The development of persistent sinuses over an area of suppuration produced by ordinary pyogenic bacteria should always suggest involvement of underlying bone or the presence of a foreign body* Fistulas that open onto the skin are of course soon colonized by microorganisms *from the external environment* Ordinary bacterial cultures of drainage fluid almost invariably show a *mixed flora and should never be relied upon for the* etiologic diagnosis of the underlying disease This is particularly important when one considers those *disorders that characteristically lead to persistent* sinus formation tuberculosis mycotic infection (actinomycosis blastomycosis) melioidosis glanders tularemia and rarely amebic abscess of the liver or cecum

Therapeutic Considerations *Recognition of the* subsidence of inflammation and striking symptomatic improvement that follow spontaneous evacuation of a suppurative focus led long ago to the adoption of *surgical incision* for the treatment of abscesses The exact *reasons for the amel*ioration of local and constitutional manifestations that results from drainage of pus are still unknown but clinically the benefits of adequate incision and drainage are unequivocal

Section 9 Infections of Specific Tissues and Anatomic Sites

Ivan L Bennett, Jr

It is traditional and convenient to classify bacterial diseases in terms of etiologic agents This is adequate for those that follow more or less consistent patterns as do typhoid anthrax brucellosis tularemia or tetanus but there are other important disorders that lend themselves poorly to categorization on the basis of causative organisms Because many microbial agents are able to invade and to localize in almost any tissue they are not regularly associated with a single symptom complex Furthermore infection of an anatomic site such as the urinary tract or the meninges by any one of a wide variety of unrelated bacterial species produces essentially the same symptoms and clinical signs Recognition of the basic pathologic process by the clinician is in most instances independent of microbiological techniques This statement is not intended to direct emphasis away from the important procedure of specific identification of infecting bacteria as a basis for choosing the appropriate antimicrobial drugs

In this section many clinical entities are described Several are more likely to be caused by certain microorganisms than others but all can be *produced by many species Most can be recognized* in their typical forms by history physical examination and clinical tests of blood and urine Final identification of the infecting agent may depend upon time consuming bacteriologic tests but a knowledge of the likely pathogens often enables the physician to initiate appropriate therapy before this information is available Surgical drainage is an essential part of proper management for several of the disorders to be described indeed surgery may be an emergency procedure for many of them necessitated not by the species of the infecting organisms but by the anatomic location of the infection

For these reasons it seems logical to describe these afflictions in terms of their manifestations in the patient Cross references to other sections of the book for details of bacteriology have been given where specific causative agents are mentioned for the diseases

143 LOCALIZED INFECTIONS AND ABSCESSES

Ivan L Bennett Jr

Localized pyogenic infection can develop in any region or organ of the body This may be initiated by *trauma* and secondary bacterial contamination by some *alteration in local conditions* that renders a tissue susceptible to organisms already present as part of the normal flora to which it is ordinarily immune by *contiguous spread* from a nearby lesion or by *metastatic implantation* of microorganisms *carried in blood or lymph*

Infection is more likely to occur in some anatomic sites than in others because of structural differences favoring localization or because of greater exposure to the risk of trauma (for example the hand)

The symptoms and signs of infection in several areas are characteristic enough to allow their clinical recognition and also to enable one to predict the pathways likely to be traversed as adjacent or distant structures become involved The definite treatment of many circumscribed infections particularly if abscess formation occurs is primarily surgical Several however are *complications of* diseases that are ordinarily cared for by the internist and the treatment of any of the serious types may call for careful integration of medical and surgical measures It is important therefore that the physician be able to recognize the major types of localized suppurative disease and know something of the principles of their management

Etiology Under appropriate conditions of lowered tissue resistance almost any of the common bacteria can initiate the infectious process Cultures from open lesions such as those of the skin or from intraabdominal foci arising from perforations of the gastrointestinal tract frequently contain several bacterial species as might be expected the organisms found most frequently are the normal flora of these regions

Infection in certain areas is more likely to be caused by certain organisms (examples being staphylococci in the skin and coliform bacteria in

interfere Abdominal or pelvic examination under anesthesia is sometimes useful in these circumstances

Auscultation may reveal a friction rub over an abdominal viscus the pleura or the pericardium The rapid development of an effusion in the pericardium pleura abdomen or a joint should suggest infection Similarly fluid detected by transillumination of paranasal sinuses or inspection of the tympanic membrane can be the first sign of infection

Depending upon the location of an abscess symptoms and signs referable to encroachment upon adjacent structures may dominate the picture Respiratory obstruction may be the first sign of mediastinal abscess dysphagia often first calls attention to peritonsillar or retropharyngeal abscesses and acute tamponade is sometimes the initial clue to pericardial infection Localizing signs of dysfunction are especially striking and important with suppurations of the brain and spinal cord (see p 975)

Local pain and tenderness or signs of dysfunction are relatively mild or equivocal in some patients *constitutional manifestations of fever prostration and weight loss* dominating the picture The fever can be low grade but is often hectic with repeated rigors and drenching night sweats Fatigue and anemia are frequent and weight loss may be so rapid as to result in emaciation within a few weeks A patient with these symptoms and signs may have chronic subphrenic perinephric or other abscess in the complete absence of any detectable physical sign pointing to the location of a huge accumulation of pus

Fluctuation of a mass on palpation is a reliable sign that it contains fluid perhaps pus but failure to detect this sign when deeper structures are examined is no guarantee that suppuration is absent and should not be taken by itself to indicate that the mass is noninfectious in origin or that drainage is not required

Laboratory Findings Peripheral polymorphonuclear leukocytosis is frequent with abscesses and unexplained elevation of the white count in any patient should lead to a search for localized suppuration Depending upon the severity and duration of infection there may be a chronic normocytic normochromic anemia Mild albuminuria is occasionally noted in febrile patients and has no diagnostic import

Pus or fluid obtained by needle aspiration or incision of a suspected lesion should *always* be stained and examined directly in addition to being cultured aerobically and anaerobically As has been mentioned pus is a poor metabolic substrate for many bacteria and organisms may fail to grow in cultures particularly from an abscess of long standing In such instances the findings on microscopic examination may be the only guide in choosing proper chemotherapy for the disease

Blood cultures are often positive in intravascular infections such as endocarditis (p 970) in pyelonephritis (p 967) and in pyogenic infections in which localized abscesses are metastatic as in staphylococcal (p 839) streptococcal (p 845) and *Salmonella* (p 888) bacteremias It should be remembered that manipulation including surgical incision of any localized infection can be followed by transient bacteremia

CLINICAL FEATURES OF INFECTIONS IN VARIOUS REGIONS

The pathogenesis diagnosis and treatment of several important infections in specific anatomic sites and organs are discussed in detail in other parts of this book These include lung abscess (p 1394) mediastinitis (p 1373) bacterial endocarditis (p 970) pericarditis (p 1281) infections of the brain and spinal cord (p 970) osteomyelitis (p 841) pyelonephritis (p 970) appendicitis and appendiceal abscess (p 1455) pylephlebitis and hepatic abscess (p 1518) pancreatic abscess (p 1477) and diverticulitis (p 1465)

The remainder of this chapter is devoted to some features of dermal infection chronic ulcerations and a consideration of a number of other important regional infections including those of the neck spleen subphrenic space kidney perirenal space retroperitoneal space and rectum

Skin and Subcutaneous Tissues

Impetigo is a superficial infection caused by hemolytic staphylococci and Group A hemolytic streptococci It is primarily a disease of children common in warm weather characterized by multiple erythematous lesions which vesiculate and are intensely pruritic Local spread occurs through scratching and release of infected vesicle fluid Serious complications are metastatic abscesses and hemorrhagic nephritis (p 863) Treatment consists of local and general cleansing of the skin application of bacitracin neomycin ointment covering with a loose dressing to prevent further contamination and appropriate systemic antibiotics

Deeper infections of the skin are almost invariably staphylococcal in origin and are described in the chapter beginning on p 839 Erysipelas a characteristic dermal lesion produced by Group A streptococci is described on p 854 and erysipeloid is described on p 918

Lymphadenitis with or without suppuration can complicate any pyogenic skin lesion and is often striking with superficial streptococcal infections

It has been learned by experience that incision of infected tissue before the stage of liquefaction and accumulation of pus is well established is often deleterious failing to relieve discomfort and facilitating spread of infection For this reason it is sometimes necessary to wait until an abscess ripens that is localizes and comes to a head It has long been known that the *application of heat* to an area of inflammation will relieve pain and often speed the subsidence of cellulitis without suppuration If necrosis of tissue is already under way hot applications appear to facilitate localization of the process and accumulation of pus making incision and drainage feasible at an earlier time Another procedure that aids in reduction of swelling and relief of pain is *elevation of the affected part*

The availability of specific chemotherapeutic drugs has modified the need for heat elevation and incision surprisingly little The early administration of sulfonamides or antibiotics has reduced the incidence of suppurative complications in many disorders but once suppuration has appeared antimicrobial drugs become remarkably incapable of eradicating the infecting organisms It is known that pus contains substances which effectively inactivate the sulfonamides and this fact alone accounts adequately for the failure of these drugs to influence localized suppurations

Antibiotics however can be demonstrated in vitro to retain their antibacterial activity in the presence of pus and necrotic tissue and the explanation of the deleterious effect of suppuration upon their therapeutic effectiveness is not simple Several factors undoubtedly contribute to the final result It is probable that failure of the drug to penetrate into an area of suppuration is rarely the reason for therapeutic failure although this possibility exists in such infections as osteomyelitis it is usually overcome by increasing dosage Because direct instillation of the antibiotic into an infected area is not by itself a curative procedure other factors are probably more important than faulty diffusion of the agent into the focus The experiments of Eagle and of Wood have shown clearly that an established inflammatory exudate is a relatively poor environment for bacterial multiplication Because penicillin s bactericidal action is exerted only against rapidly multiplying organisms it is now believed that failure of this antibiotic to eradicate bacteria in an abscess is related to their *relatively inactive metabolic state* Because a bacteriostatic agent such as tetracycline or chloramphenicol is capable only of inhibiting multiplication of bacteria and usually exerts no direct lethal action the final death of organisms in any infection treated with agents of this type is dependent upon other mechanisms For most pyogenic bacteria *phagocytosis is one of the most important* of these mechanisms (although there must be others that have not been as carefully studied) and it is now known that in the absence of phagocytes or in circumstances which inhibit their activity bacteriostatic drugs are relatively ineffective In fluid filled cavities and particularly *in the metabolically unfavorable* milieu of an abscess phagocytosis is greatly reduced and consequently despite inhibition of multiplication bacteria can remain dormant and survive for long periods of time It is probably a combination of these two circumstances decreased multiplication of bacteria and decreased phagocytosis that makes infection on the heart valves in the kidney or in the meninges as well as soft tissue abscesses so resistant to antibiotic therapy Administration of large doses of bactericidal drugs for long periods often becomes necessary to achieve cure

From a practical viewpoint antimicrobial drugs can be expected to prevent suppuration if given early enough or to prevent spread of an already existent abscess but they cannot be substituted for surgical drainage Indeed their use in the face of a lesion requiring evacuation of pus is one of the most common serious errors in treating infections

In thoracic empyema suppurative pericarditis or pyarthrosis excellent therapeutic results are sometimes achieved by aspiration of pus through a needle and instillation of antibiotics into the infected area The success of this procedure however *is fully as dependent upon the adequacy of the* drainage that it achieves as it is upon the local application of the antibiotic and if there is loculation or the exudate becomes too viscid to allow removal surgical incision becomes mandatory

In the presence of infective thrombophlebitis surgical interruption of the veins by ligation or in certain instances by total excision of an infected segment is often indicated to prevent seeding of other organs by infected emboli

Manifestations Secondary infection of wounds and cutaneous ulcers is usually recognizable by inspection Infections of the skin and subcutaneous tissues almost invariably produce the classic manifestations *redness tenderness heat* and *swelling* Reddish streaks extending proximally and associated with tender enlargement of regional lymph nodes indicate lymphangitis Systemic symptoms can be absent or mild or there can be fever *malaise prostration* and leukocytosis

Infection and suppuration in deeper tissues or in body cavities is often manifested by local pain and tenderness but the task of locating and determining the exact nature of the lesion can be difficult The palpation of a tender mass is helpful but muscle spasm and intervening structures often

systemically or locally administered antimicrobial drugs the predominating bacterial species show great variation when lesions are cultured serially Particularly noteworthy is the replacement of sensitive organisms by resistant strains or species in the course of chemotherapy

Treatment of chronic dermal ulcers should be directed toward the underlying disorder but should also include *local debridement* and *chemotherapy* Debridement by surgical excision is often needed but the local application of proteolytic enzymes such as Varidase a mixture of streptokinase and streptodornase or trypsin so called "chemical or medical debridement is sometimes sufficient Intensive systemic administration of antibiotics should be carried out only in conjunction with definitive surgical procedures or when infection can be controlled in no other way but the prevention of infection by prophylactic administration of antimicrobial drugs is a hopeless task The result will be the development of a flora resistant to the drugs being used The *local application of antibiotics* is sometimes highly effective and it is in the management of chronic mixed infections of this type that several potent but toxic antibiotics have great value The topical use of an ointment or solution containing neomycin bacitracin and polymyxin results in a bactericidal effect against a wide variety of organisms and will sometimes temporarily sterilize a chronic lesion Other useful topical medications are Furacin and 3 per cent acetic acid the latter being especially helpful in *Pseudomonas* infections

Infections of the Head and Neck

Mention may first be made of the peculiar danger of pustules of the nose and upper lip because of the likelihood of extension of infection intracranially through the angular vein to the cavernous sinus (see p 978) Such lesions should be treated conservatively manipulation or incision being avoided if possible and systemic antibiotics being given if local swelling or redness appears

Suppurative parotitis is usually a complication of chronic debilitating disease or blockage of Stensen s duct by a calculus and is largely avoidable by maintenance of hydration and oral hygiene Its onset is heralded by local pain and swelling fever and chills are frequent Frank pus can sometimes be expressed from the duct and the gland itself is firm and tender often with pitting edema of the overlying skin In severe cases there may be facial palsy on the involved side Removal of any obstruction in the duct application of heat and administration of antibiotics sometimes leads to prompt subsidence of local and systemic signs However incision is still required in many cases and *failure of a patient to respond promptly to these more conservative measures is an indication for surgical drainage* Abscess formation may be far advanced without there being detectable fluctuation because of the dense fibrous capsule of the gland Before chemotherapy was available the mortality rate in pyogenic parotitis was 30 to 50 per cent

The use of penicillin and other antibiotics has reduced the incidence of many formerly common suppurative complications of streptococcal pharyngitis (see p 845) However as a result of streptococcal sore throat *Bacteroides* infections of the pharynx (see p 882) or introduction of infection by trauma to the floor of the mouth or the pharyngeal wall abscesses of the deep cervical structures still occur *Suppurative cervical adenitis* once an all too common sequel to streptococcal pharyngitis in children is now rare *Peritonsillar abscess* or *quinsy* is manifested by fever sore throat unilateral pain radiating to the ear on swallowing and enlargement of the tonsil with redness and swelling of the adjacent soft palate Treatment with penicillin and irrigations of warm saline sometimes leads to subsidence of the process but if digital palpation reveals fluctuation surgical drainage with or without tonsillectomy is indicated

The course of *deep cervical infections* is fully as dependent upon the anatomical arrangement of fascial planes as is that of infections of the hand There are five important potential compartments in the anterior neck these are described in detail in the article by Barnhill listed at the end of the chapter Infection in any of these areas is serious and attended by fever prostration and leukocytosis A tender mass may be palpated but it is to be emphasized that *surgical evacuation of such an infection should not be delayed because of failure to detect fluctuation* which is usually absent because of the dense fascial layers

Infection of the *sublingual space* so-called Ludwig s angina is characterized by brawny induration of the submaxillary region edema of the floor of the mouth and elevation of the tongue There is severe pain dysphagia and within hours dyspnea from respiratory obstruction The usual causative organism is the streptococcus Mortality was formerly about 50 per cent *Treatment* consists of large doses of penicillin and careful observation If there is significant progression of obstruction during the 4 to 6 hr after treatment is instituted wide incision is indicated for relief of pressure rarely is there extensive suppuration

The retropharyngeal space lies between the muscles anterior to the cervical vertebrae and the pharyngeal mucosa *Retropharyngeal abscess* formerly common in children is manifested by

Specific diseases characterized by suppurative regional lymphadenitis include lymphogranuloma venereum (p 1096) cat scratch disease (p 1098) tularemia (p 905) and bubonic plague (p 907)

Infections of the Hand

These are almost invariably secondary to trauma and are very common Because of the rapidity with which infection can spread through the complex fascial spaces of the hand wrist and forearm with the production of irreparable functional damage *any deep infection in this area should receive expert surgical attention immediately* The importance of this has in no way been lessened by the availability of antibiotics

The ordinary *paronychia* or "run around" is a superficial infection of the epithelium lateral to a nail usually a result of tearing a "hangnail" and most frequently caused by the staphylococcus Hot applications will lead to subsidence of paronychial cellulitis but often a superficial blister of pus appears or the infection burrows beneath the nail to form a painful *subungual abscess* Incision and drainage with partial or complete removal of the nail are then necessary Recurrence is common especially in nail biters and this seemingly trivial infection can cause painful disability Chronic paronychial inflammation produced by various fungi occurs in diabetics and a similar lesion is seen in psoriasis and some types of pemphigus

What appears to be a small furuncle of the webs of the fingers sometimes produces a *collar button abscess* consisting of a superficial and a deep compartment connected by a narrow tract evacuation of the shallow pocket without emptying the deeper abscess can lead to puzzling persistence of infection

Infection of the distal phalanx of a finger usually acquired by pinprick thorn prick etc can lead to the formation of a *felon* or *whitlow* This is a suppurative infection in the tightly enclosed fibrous compartments of the finger pulp (the anterior closed space) which can soon compromise the distal blood supply by compression of the digital arteries with consequent necrosis of bone and the development of osteomyelitis The manifestations are swelling extreme pain and tenderness of the *palmar surface of the fingertip The treatment is* immediate incision using a lateral approach and cutting all the fibrous septa that radiate from the periosteum to the subcutaneous fascia

Suppurative tenosynovitis usually a complication of a puncture wound is an even more serious infection of the hand from the point of view of functional damage early diagnosis and treatment are mandatory to prevent permanent disability from destruction of the tendon or its sheath The three cardinal manifestations of tenosynovitis listed by Kanavel the father of modern surgery of the hand are (1) exquisite tenderness limited to the course *of the sheath (2) the fingers held in flexion (3)* extension of the involved finger producing excruciating pain most marked at the base of the digit *Immediate incision* of the sheath is indicated not only to prevent damage to the tendon itself but to avoid proximal extension of the process into the major fascial spaces of the hand or forearm Vigorous *antibiotic treatment should accompany the* surgery

The definitive treatment of any serious infection of the hand is a matter for a skilled surgeon but the early recognition of the need for surgery often falls to the physician One last infection of the hand that is very important is that complicating *human bites* Neglected injuries of this type almost invariably produce a highly destructive necrotizing lesion the result of infection by a mixture of aerobic and anaerobic organisms A deliberately inflicted bite on the hand or elsewhere is usually recognized as dangerously contaminated but wounds on the knuckles produced by striking an opponent s teeth with the fists may not be recognized as potentially dangerous *In general bite wounds should be* cleaned thoroughly and *not* sutured patients should be given prophylaxis for tetanus and antibiotics preferably penicillin and streptomycin and observed carefully

Chronic Cutaneous Ulcers

A partial list of the causes of chronic ulcers of the skin includes circulatory disturbances such as varicose veins and obliterative arterial disease extensive injury from frost bite or burns trophic changes accompanying many neurologic disorders bedsores or decubiti systemic diseases such as sicklemia and myxedema neoplasms and several infections of mycotic and spirochetal origin No matter what the underlying disease responsible for the lesion secondary infection is very likely to occur and to interfere with healing complicate grafting or other restorative procedures or produce extension of the process

The management of secondary bacterial infection in skin ulcers associated with obliterative arterial *disease a common problem in diabetics* is especially important because infection is frequently the factor that precipitates spreading gangrene and makes amputation necessary

Studies of the microflora of chronic cutaneous ulcers have almost invariably shown bacteria of many species including *staphylococci* aerobic and anaerobic streptococci coliform bacilli and members *of the Proteus and Pseudomonas* groups Depending upon the patient s environment and upon

many surgeons prefer to explore the area by needle aspiration before operation

Retroperitoneal Infections

Strictly speaking all perinephric and many subphrenic abscesses are located outside the peritoneum but the term *retroperitoneal abscess* usually refers to infection in the lumbar and iliac regions Suppuration in these areas is relatively rare but the importance of recognizing its existence in patients with fever and low back pain in terms of instituting surgical drainage is great In the review of retroperitoneal infections published by Neuhof and Arnheim listed in the references at the end of this chapter the average duration of illness in 65 patients before diagnosis was approximately 1 month

Infection in the retroperitoneal spaces appears to arise rather frequently as a complication of bacteremia particularly in staphylococcal disease Other sources are extension from posterior perforations of the appendix or colon renal or spinal infections and suppurative lymphadenitis in the iliac area usually secondary to streptococcal infections of the lower extremity in children

In *lumbar abscess* there is tenderness and spasm of the back muscles on the affected side and a mass is usually palpable in the lumbar region or in the abdomen There may be a prominent tender abdominal mass without lumbar pain or spasm Flexion of the hip (psoas sign) occurs in a few cases but is more often present with infections lower in the retroperitoneal area *Fever leukocytosis* and *lumbar spasm* should suggest the diagnosis The absence of a palpable mass can lead to protracted observation and it is in these instances that palpation under anesthesia is often helpful

In *iliac abscess* there is abdominal pain in the iliac or inguinal region and particularly when the psoas muscle is involved there may be severe pain referred to the hip thigh or knee Careful palpation of the lower abdomen usually reveals a mass and fullness and tenderness on rectal examination are common Hip spasm (psoas sign) is often present

X ray may delineate the inflammatory mass pyelography shows displacement of the kidney in some cases of lumbar infection scoliosis with concavity on the side of the infection and blurring of the psoas shadow are also useful findings

Treatment consists of surgical drainage and appropriate antibiotic therapy

Renal Abscess

Single or multiple abscesses of the renal cortex are almost invariably the result of metastatic implantation of staphylococci from another focus It is believed by many that the infection is initiated in glomeruli There is no relationship to previous renal disease the infection occurs in younger individuals is usually unilateral and occurs on the right side oftener than the left Many patients give a history of recent superficial infection such as furuncle The onset is abrupt with chill and fever followed by costovertebral pain and tenderness of moderate severity The urine contains *no white cells* usually a few red cells and a trace of albumin Stained urinary sediment will show myriads of gram positive cocci and this finding is diagnostic Transient gross hematuria can occur at the onset The white blood count is usually elevated and may exceed 30 000 per cu mm Physical signs are usually localized to the region of the kidney but abdominal spasm can lead to confusion with appendicitis or cholecystitis Early in the disease ureteral calculus or acute hydronephrosis may be considered as possible diagnoses Sudden onset of fever leukocytosis and renal pain in the absence of pyuria suggest the diagnosis especially in a patient with infection elsewhere *Treatment* consists of appropriate antibiotics adequate fluids and relief of pain An abscess may suddenly discharge into the renal pelvis with relief of pain and the passage of cloudy urine containing enormous numbers of leukocytes and bacteria *Complications* include formation of a thick walled chronic renal carbuncle" requiring surgical removal rupture into the perirenal space and secondary pyelonephritis usually produced by coliform bacilli Recovery is ordinarily prompt and chronic sequelae are rare

Perinephric abscess is virtually always secondary to infection elsewhere in the body usually superficial staphylococcal or streptococcal infection The perirenal tissue may be seeded directly in the course of bacteremia by rupture of a renal cortical abscess into the perinephric space or by chronic pyelonephritis particularly when renal calculus or pyonephrosis is present Flank pain with radiation to the upper abdomen or even the shoulder nausea vomiting fever leukocytosis tenderness with spasm of flank and upper abdominal muscles and a palpable mass which moves with respiration are the main manifestations Except where there is preexisting pyelonephritis perinephric abscess is *not* accompanied by urinary symptoms In a few patients elevation of the diaphragm on the diseased side occurs and leads to confusion with subphrenic infection The psoas muscle is involved by the inflammatory process and patients are frequently more comfortable with the thigh held in flexion X ray occasionally will reveal a mass there is usually blurring of the kidney silhouette and the psoas shadow is indistinct on the involved side *Treatment* by surgical drainage and systemic administration of antibiotics (*not* urinary antiseptics) is usually followed by dramatic subsidence of pain and fever

dysphagia progressive stridor pain and fever The bulging mass is easily seen and can completely occlude the airway within hours Incision and drainage are mandatory spontaneous rupture can lead to death by aspiration Tuberculous abscess secondary to spinal disease occasionally presents in the retropharyngeal space it is painless and relief of obstruction follows surgical incision The pharyngomaxillary and submastoid spaces lie high and lateral in the neck the latter slightly posteriorly *Suppuration in the submastoid space a Bezold abscess* is usually secondary to otitis and produces nuchal rigidity which may lead to a mistaken diagnosis of otogenous meningitis Infection can extend down the carotid sheath to the mediastinum A suppurative thrombophlebitis of the jugular vein usually accompanies this type of spread and the vessel is easily felt as a tender cord Bacteremia and systemic spread of infection makes this a dangerous complication there are many who advocate excision of the involved venous segment Spontaneous rupture of the carotid artery and rapid death from exsanguination is a rare complication of infections of this type

Splenic Abscess

The majority of splenic abscesses are produced by hematogenous dissemination of infection from a focus in the skin endocardium or elsewhere Trauma to the spleen with formation of a sub capsular hematoma or bland infarction of the organ can lead to infection in the course of transient bacteremia Occasionally extension of a nearby infection (usually left subphrenic abscess) or perforation of the colon or stomach into the spleen is the source Onset is sudden with chills fever and left upper quadrant pain There is tenderness and muscle spasm and the skin and subcutaneous tissues overlying the spleen may be edematous In volvement of the upper pole commonly leads to left pleuritic pain radiating to the shoulder with elevation of the diaphragm or left pleural effusion Lower pole abscess gives signs of peritoneal inflam mation The spleen is usually palpable and tender a friction rub is often audible Disorders to be considered in differential diagnosis are subphrenic *abscess infection of the left lung bland infarction* of the spleen pancreatic pseudocyst and abscess secondary to perforation of the transverse colon *Treatment* consists of antibiotics and splenotomy or if the organ is easily mobilized splenectomy If the abscess is a complication of generalized pyogenic infection immediate surgery may be contraindicated Splenic infarction in subacute bac terial endocarditis caused by *Streptococcus viridans* almost never suppurates but in endocarditis in fected splenic infarcts are a rare cause of continued bacteremia in the face of massive chemotherapy and splenectomy may then be the treatment neces sary *to achieve the final eradication of the* or ganism

Subphrenic Abscess

Peritoneal infections show a striking tendency to localize in the upper part of the abdomen between the transverse colon and the diaphragm In a few instances suppuration in this area seems to be hematogenous in origin but the vast majority of subphrenic abscesses are the result of extension from perforations of the gastrointestinal tract or from biliary tract infections The most frequent sources of infection are appendicitis perforations of the stomach and duodenum and ascending cholangitis *Any patient with persistent fever and a history of recent intraabdominal sepsis should be suspected of having a subphrenic abscess* In considerably more than half of the cases the patient has undergone recent laparotomy The avenues by which infection reaches the subphrenic region are the same as those described for hepatic abscess (p 1518) and appendical abscess (p 1455) Sub phrenic abscess is at least five times more frequent on the right side

The *manifestations* include fever upper quadrant pain and tenderness The localizing signs are by no means striking in all cases however It is becom ing evident that the widespread practice of "cover ing postoperative patients with antibiotics prophy lactically can attenuate subphrenic infection with out eradicating it and that the result may be an insidiously progressive illness with weight loss and low grade fever beginning weeks or months after a laparotomy Faxon has emphasized the fol lowing findings in the diagnosis of subphrenic in fection point tenderness over the lower ribs tenderness of the area when the lower rib cage is compressed or percussed elevation and fixation of the diaphragm confirmed by x ray other signs of diaphragmatic pleurisy such as pain referred to the shoulder hiccoughs or pleural effusion X rays will show an air fluid level beneath the diaphragm eventually in about one fourth of the cases but this finding is less frequent in early abscess The gas is usually from a perforated viscus or enters *through an external sinus* and is only rarely the result of bacterial multiplication

In the presence of frank suppuration the treat ment is surgical drainage Actually there are several subphrenic spaces anterior and posterior and the exact incision *employed is dependent upon the* compartment involved Often subphrenic infection becomes evident before suppuration ensues and such cases of *subphrenic cellulitis* often subside without drainage antibiotics alone being sufficient to control the process *It is important to avoid in* cision of an area of subdiaphragmatic cellulitis and

144 INFECTIONS OF THE URINARY TRACT (Including Pyelonephritis)

Paul B Beeson

Bacterial infections of the urinary tract constitute one of the major medical problems encompassing all fields of practice They may present themselves as primary acute infectious diseases as complications of other disorders or as chronic symptomless processes chiefly dangerous because of the threat of gradual destruction of the kidney They are notoriously resistant to treatment and prone to relapse and recurrence

Etiology Many different microorganisms may infect the tissues and fluids of the urinary organs but by far the commonest are the coli aerogenes group of gram negative bacilli Other microorganisms which may be found include enterococcus Proteus Pseudomonas Chromobacteria staphylococcus and certain yeasts Infection by other than the coli aerogenes organisms is generally related to previous instrumentation of the urinary tract with or without the use of chemotherapeutic agents *Proteus* and *Pseudomonas* urinary infections for example are virtually never seen except in patients who have had catheters or other instruments passed through the urethra The relative importance of staphylococcal infections has probably been exaggerated in the past because of the prevalent custom of culturing urine only in a liquid medium a procedure which negates any possibility of estimating the numbers of bacteria present in a given quantity of urine Since staphylococci are commonly present in the urethra they may therefore be recovered in such cultures The employment of quantitative bacteriologic techniques reveals that staphylococci play a minor role in the total problem of urinary tract infection

Pathogenesis *Sources of Infection* The entire urinary tract should be looked upon as an anatomic unit in which infection of one part can easily spread to another While it is probable that the source of infecting bacteria is the intestinal tract there is considerable disagreement regarding the routes by which microorganisms usually get from there to the urinary tract One view holds it to be by way of the circulating blood another favors the concept that bacteria gain entry by way of the urethra and pass upward to the kidneys through the bladder and ureters The latter seems especially plausible as an explanation of the far greater frequency of spontaneously occurring infections in females since the short urethra and its nearness to the anus should provide more opportunity for fecal bacteria to reach the bladder cavity A third hypothesis that lymphatic connections between the bowel and the urinary tract or between the lower and upper urinary tracts are important avenues for spread of infection has little to support it On the basis of clinical correlations there is much evidence favoring the view that the ascending route i e lower to upper urinary tract via the urinary passages is the most important one The possibility remains however that bacteria occasionally are carried to the kidney by way of the blood stream thus inciting an infection which later spreads downward along the course of urinary flow

Associated Conditions AGE AND SEX Precise estimates cannot be given but it can be said with assurance that urinary tract infections are far more frequent in females than in males except in older age groups where prostatic obstruction accounts for a high incidence in males There is also a high incidence in children between the age of six months and two years especially females this is thought to be related to fecal soiling of the urethral meatus during the diaper period

PREGNANCY Acute pyelonephritis occurs in about 2 per cent of pregnant women usually after the fourth month at a time when some dilatation of the ureters and kidney pelves occurs physiologically Urinary tract infection can be demonstrated in about 20 per cent of patients with toxemia of pregnancy

DIABETES MELLITUS Urinary tract infection is three or four times as common in diabetics as in other persons of comparable age Factors which may contribute to this include the supposed increased susceptibility to infection in diabetics the enhanced growth of bacteria in sugar-containing urine and more frequent catheterization About half of all reported cases of the fulminating form of pyelonephritis called *necrotizing papillitis* have been in patients with diabetes

OBSTRUCTIVE UROPATHY Any impediment to the free flow of urine—tumor stricture or stone—results in hydronephrosis and a greatly increased frequency of urinary tract infection Autopsy statis

and unless intrinsic renal disease is present recovery is complete

Rectal Abscess

Suppurations of the anorectal region have been classified anatomically in several ways most of the classifications being based upon the surgical approaches required for drainage Infection in the apocrine glands (hidradenitis) or folliculitis in the perianal region extension of cryptitis or obstructions in the anal glands which open into the crypts of Morgagni and contamination of submucosal hematomas sclerosed hemorrhoids or anal fissures can lead to abscess formation These are *usually painful easily palpable often visible* on inspection and yield readily to hot applications and drainage

Difficulties in diagnosis are more likely to arise with infections higher in the rectum especially those above the pelvic diaphragm the types that Gaston and Warren have called *supralevator abscess* Patients with this type of infection often have fever malaise and leukocytosis for several days or even weeks before any symptoms referable to the rectum develop There is vague pelvic discomfort relieved by defecation and constipation punctuated by short episodes of diarrhea is common In males the inflammation often involves the base of the bladder and urinary urgency and finally retention is not infrequent This of course centers attention upon the urinary tract as a source of fever and malaise Eventually the abscess becomes known by severe pain chills and fever and palpation and instrumentation will reveal the swelling in the rectal ampulla Such an abscess can surround the rectum and produce narrowing that is differentiated from that caused by neoplasm by the fact that the mucosa remains intact A useful sign of deep rectal abscess is the eliciting of severe pain by pressure in the region between the anus and the coccyx The supralevator space is continuous with the ischiorectal space with both the gluteal and obturator regions and with the retroperitoneal space In neglected cases the abscess may drain through the skin of the perineum the groin or the buttock or may extend as high as the perirenal areas Rectal abscesses are not uncommon in patients with diabetes and infections in this area are also peculiarly frequent in patients with monocytic leukemia Because the clinical picture may be that of fever of unknown origin for a long period it is important that thorough digital and endoscopic examination of the rectum be carried out in febrile patients A rectal examination should be made in all patients with diabetes especially if ketosis is present failure to observe this rule has more than once led to delay in detecting the infection responsible for diabetic ketosis or coma

Treatment consists of incision and drainage hot sitz baths analgesics and penicillin and streptomycin or other antibiotics as indicated by culture of the exudate

cystitis are usually associated and either one may precede the other

On physical examination in addition to fever and some generalized tenderness of the muscles the key finding is tenderness on deep pressure in one or both costovertebral areas or on bimanual palpation of the kidney region Occasionally even this sign is absent in acute pyelonephritis

Except in individuals with ureteral obstruction as by stone the manifestations of acute pyelonephritis usually subside within a few days even without specific antibacterial therapy the patient becoming symptom free although laboratory tests may show that bacteriuria and pyuria are still present It would seem therefore that after the first acute inflammation in the renal parenchyma with swelling and perhaps intermittent plugging of the ureter by inspissated pus to account for the pain there ensues a change in character of the disease with the parenchymal infection going over to a more indolent process involving many small foci in the kidney substance but with continuing growth of bacteria in the kidney pelvis and the descending urinary passages

Undoubtedly some individuals recover completely and permanently after an attack of acute pyelonephritis but in a considerable proportion of cases there are repeated attacks at irregular intervals sometimes over a period of many years between these the patient is symptom free It is possible however that bacilluria and pyuria could be demonstrated during these free intervals if looked for repeatedly The important point to be stressed is that infection in any part of the urinary tract is capable of subclinical continuation which may persist for months or years and which in the kidney eventually may cause serious destruction of essential tissue Such a patient may exhibit no symptoms and may live an apparently normal life for long periods even though urine examination gives continuing evidence of active infection This is the feature which makes it so treacherous and such an important cause of serious renal disease

In the *chronic progressive form of pyelonephritis* there are no distinctive manifestations until one of the serious complications makes its appearance i e renal failure or hypertension Before this time there may be some lassitude lack of energy and mild normochromic anemia Occasionally patients with long standing pyelonephritis are found to have large spleens the pathogenesis of which is obscure

Laboratory Findings In acute pyelonephritis there is a polymorphonuclear leukocytosis in cystitis and in chronic urinary tract infection the white blood cell picture is normal The urine sediment in acute pyelonephritis or cystitis usually reveals numerous leukocytes occurring singly in clumps and in casts and occasionally some red blood cells Bacteria can easily be demonstrated by suitable stains In chronic infections of low grade activity diagnosis may be very difficult on the basis of urine sediment There may be a few pus cells or they may be found only intermittently during repeated urinalyses Special stains for the so-called "glitter cell are thought by some to be of value in pointing to the presence of chronic pyelonephritis although the demonstration of this cell cannot be regarded as diagnostic

Culture of the urine is the most important diagnostic procedure In acute pyelonephritis bacteria are nearly always demonstrable in large numbers sometimes hundreds of millions of them per milliliter In subacute and chronic infections bacteria may appear in the urine intermittently and in relatively small numbers Consequently inasmuch as urine cultures may be contaminated by small numbers of bacteria lying in the urethral canal even in a specimen obtained by catheter it is important that the laboratory employ some quantitative method for determining the number of organisms present in the urine and that the urine be cultured on a solid medium in order to estimate the relative preponderance when mixed growth is obtained A rough quantitative estimate of the situation can be made by means of a Gram stain on uncentrifuged freshly voided urine If bacteria can be found by this method it can be assumed that the number present is greater than would be expected to occur as a result of urethral contamination If quantitative cultures reveal more than 10 000 bacteria per milliliter of freshly passed urine it can be assumed that active infection is present If less than 1 000 they are likely to be of no significance Between these two figures one cannot draw a positive conclusion *Intravenous pyelogram* may be of value in the diagnosis of pyelonephritis evidenced by an asymmetry between the kidneys as judged by their size and the density of the renal shadows This of course is a reflection of the patchy distribution of the pyelonephritis lesion It is said also that careful radiographic studies will show hypotony of the calyces pelvis and ureters in a high proportion of these cases *Biopsy of the kidney* by needle may be the only means of demonstrating low grade pyelonephritis but its value is also limited by the spotty distribution of the lesions However culture of the biopsy needle occasionally yields bacteria even when the histology is inconclusive

Treatment The soundest approach to treatment is based upon a conception of the urinary tract as a complex system wherein infection introduced into or persisting in any one part may spread to all the others For example certain drugs which have been recommended for treatment of urinary tract infection appear to be capable of acting only in urine These which include mandelic acid Urotropin

tics indicate that pyelonephritis occurs about a dozen times more often when there is hydronephrosis than when the kidneys show no sign of increased hydrostatic pressure

INSTRUMENTATION There can be no question that infection of the lower urinary passages is sometimes initiated by bacteria carried on catheters or other instruments being passed through the urethra into the bladder

METABOLIC DISORDERS There appears to be an unusually high incidence of urinary tract infection in patients with nephrocalcinosis and in those with chronic hypopotassemia The relation of the latter is obscure in nephrocalcinosis the important factor may be production of tubular obstruction by the deposits

NEUROGENIC BLADDER DYSFUNCTION Interference with the nerve supply to the bladder as in spinal cord injury tabes dorsalis multiple sclerosis etc is likely to be associated with urinary tract infection The infection may be initiated by the use of catheters for bladder drainage and favored by the prolonged standing of urine in the bladder Additional factors which often operate in these patients are bone demineralization due to immobilization hypercalcuria calculus formation and obstructive uropathy

Urinary tract infections can be produced in experimental animals by several methods including inoculation of bacteria into the pelvis or substance of the kidney or into the bladder urine Certain organisms such as staphylococci and Monilia are capable of causing infection in the normal kidney when they are injected by the intravenous route Coliform organisms will not do this unless the kidney has previously been injured as by mechanical bruising or acute obstruction of the ureter It has also been shown that the renal scarring resulting from a staphylococcal infection can render the kidney susceptible to infection by colon bacilli injected intravenously

The frequent association of urinary tract infection with an obstructive lesion has led to the widespread view that stasis of urinary flow is a prime factor in the development of infection In support of this is the fact that urine is a good medium for growth of bacteria hence prolonged opportunity for multiplication during slow passage along the tract would provide a heavier inoculum to which the kidneys and other tissues of the tract are exposed This concept is the basis for the custom of forcing fluids in treating urinary infections There may be an additional factor to explain the association between obstruction and urinary infection the effect of increased hydrostatic pressure One can cite several examples where clinical experience demonstrates that blockage to an excretory duct seems *to render an organ more susceptible to the* development of pyogenic infection For instance bacterial cholangitis is seldom encountered except when there is obstruction to the biliary passages It seems unlikely that the mere flushing out of bacteria in the excretory fluid could be the sole *factor of protection against these infections* To assess the relative importance of stasis and increased pressure is difficult since slowing of flow of the fluid is an inevitable accompaniment of obstruction and dilatation of the passages above the level of obstruction It can be said with assurance that even when a profuse diuresis is obtained in a patient with partially obstructed urinary tract this seldom achieves cure of an infection whereas relief of the obstruction with or without diuresis frequently is followed by subsidence of infection

In urinary tract infection two different infected areas are interacting the tissues and the urine itself On the basis of animal experiments and clinical observations it seems clear that infection beginning in one can spread to the other The complexity and extent of the urinary system may be responsible then for the tenacity of infection in it One conceives of chronic pyelonephritis as an indolent process consisting of many isolated microabscesses some of them within single tubules Here bacterial growth may be slow phagocytosis inefficient and antibacterial drugs may not be capable of exerting optimal effect Yet such areas may from time to time discharge their contents into the urinary passages affording opportunity for rapid bacterial multiplication and spread to other parts of the system In the urine phagocytosis is probably even less effective than it is in tissues and elimination of bacteria may call for more than simple bacteriostasis This line of reasoning leads to the conclusion that optimal results in drug treatment require the use of an agent or a combination of agents capable of killing the infecting bacteria both in the tissues and in the urine

Manifestations *Cystitis* is accompanied by pathognomonic local symptoms frequency and urgency of micturition and burning pain *felt in the* urethra during and immediately following the act Cystitis alone almost never gives rise to prominent systemic manifestations of infection such as fever above 101 F muscular pain nausea vomiting and prostration and when present these should cause the physician to suspect concomitant infection in the kidney prostate or some other part of the body

The symptoms of *acute pyelonephritis* generally develop rapidly over a period of a few hours or a day or two The characteristics are aching pain in one or both lumbar regions and fever which may be high (103 to 105 F) often with one or more shaking chills There may be nausea vomiting and diarrhea or occasionally constipation Symptoms of

SUBACUTE BACTERIAL ENDOCARDITIS DUE TO VIRIDANS STREPTOCOCCI

Definition This is a prolonged febrile often fatal disease resulting from streptococcal infection of a heart valve characterized by fever heart murmur splenomegaly embolic phenomena and bacteremia

Etiology The viridans group of streptococci includes several different varieties (p 868) Those which are important causes of subacute bacterial endocarditis are *Streptococcus salivarius* *S mitis* and *S bovis* normally present in the mouth the enterococcus *S fecalis* normally present in the intestinal tract and *S sanguis* which has been encountered mainly in cases of bacterial endocarditis

Pathogenesis In the great majority of cases bacterial infection is established on a valve which has been previously damaged by rheumatic fever Changes caused by congenital heart disease or rarely by arteriosclerosis or syphilis may also provide the foundation for this infection The mitral valve is the one most often involved the aortic is second in frequency The valves on the right side are affected far less often i e in only about 15 per cent of cases including those in which the mitral and aortic are also involved This corresponds with the frequency of involvement of the four valves in rheumatic heart disease Valves only slightly damaged appear to be more frequently affected than those which are extensively scarred This is partly attributable to the fact that people live longer with slightly damaged than with severely damaged valves and hence have more opportunity to contract the infection but other factors which may play a part include turbulence of blood flow over the valve the circulation within the valve and the amount of scar tissue present It is generally agreed that bacterial endocarditis rarely occurs in persons with chronic auricular fibrillation

A similar process may become established on a patent ductus arteriosus at the site of coarctation of the aorta or in an arteriovenous fistula. These infections are called subacute bacterial *endarteritis*

Bacteria must reach the heart valves by way of the blood stream There is abundant evidence to show that entry of bacteria into the circulation is not infrequent For example it is a common occurrence in minor surgical procedures such as tooth extraction and tonsillectomy Bacteremia can occur in persons with periapical dental infection simply as a result of grinding the teeth together Ordinarily such brief episodes of bacteremia are not serious because the organisms are quickly phagocytized by the reticuloendothelial system If however living bacteria happen to lodge in or on a damaged heart valve the stage has been set for the establishment of a grave infection The manner in which a colony of bacteria becomes established in such a location is not known with certainty The fact that preexisting deformity of the valve is usually a requirement brings up the possibility that roughening of the endocardial surface or some change in blood supply to a valve may predispose to implantation of the infection Possibly the bacteria become lodged beneath small platelet thrombi on the surface of a valve Possibly they are carried into a valve through its blood supply and are deposited beneath the endocardium In any event the primary site of bacterial growth is usually near the free edge of the valve at the line of closure and on the outflow surface This growth stimulates the deposition of platelets and fibrin and leads to the formation of a *vegetation* This structure increases in size and may extend onto the adjacent mural endocardium Meanwhile the valve leaflet is undergoing gradual necrosis Granulation tissue grows into the vegetation from the valve but capillaries seldom reach the periphery of the infected necrotic area Nests of growing bacteria are scattered through the vegetation those which are in the avascular outer portion of the vegetation are protected from phagocytosis since leukocytes do not seem able to penetrate the area This protection from phagocytosis may be the principal factor which permits survival of bacteria and persistence of the infection and which accounts for the unsatisfactory therapeutic results obtained with drugs which are only bacteriostatic

Organisms are constantly shed into the blood from the vegetation but their stay in the circulation is very short, since studies have shown that one-half to one-third of the organisms entering the arterial blood are removed during each circuit of the body The principal sites of removal are organs rich in reticuloendothelial elements—i.e liver spleen, and bone marrow

Vegetations of bacterial endocarditis are friable and fragments are occasionally broken off by motion and the current of blood passing over them These particles are carried in the blood to all parts of the body where they eventually lodge as emboli The damage produced by an embolus depends principally on its size and the vessel which happens to receive it Emboli which lodge in the brain in the mesentery or in arteries of the extremities are most likely to have serious effects Those carried into the walls of large arteries by vasa vasorum can cause mycotic aneurysms which may rupture at a later time

It should be noted that the infected emboli and the free bacteria which are constantly disseminated throughout the body very seldom create metastatic abscesses The infecting organisms are usually of

and nitrofurantoin (Furadantin) often suppress but do not eradicate infection The antibiotics are generally also effective in tissues although some are more likely to exert a bactericidal action than others Sulfonamides are principally bacteriostatic Another essential principle in management is to consider what factors in the patient may be contributing to the infection such as obstruction faulty bladder innervation diabetes etc these were mentioned in a preceding section Relief of obstruction or correct management of diabetes may be the essential factor in eradicating the infection Although no further space will be devoted to this aspect of treatment its importance cannot be overemphasized

In antibacterial therapy best results are obtained when there is individualization of the treatment Advertisements and medical articles which describe the effectiveness of any one agent in the treatment of urinary infections are misleading There is a wide choice of agents which may be used and the best results are obtained by employing the therapy suited to the microbes operating in the individual patient

In view of the varying conditions under which bacteria grow in urine and in urinary tract tissues it seems probable that the ideal chemotherapeutic attack is to employ a form of treatment which is capable of bactericidal not simply bacteriostatic action Determination of possible synergistic or antagonistic effects of combinations of agents on the bacteria to be attacked is sometimes necessary Streptomycin is perhaps the most valuable of all agents available its main defect being the rapidity with which bacteria develop resistance to it this defect can be lessened however by giving streptomycin in combination with another antibiotic such as tetracycline Enterococcus infections may yield to a combination of penicillin and streptomycin For *Proteus* infections the antibiotics most likely to be beneficial are penicillin in massive doses or neomycin For *Pseudomonas* infection polymyxin may be required Since the use contraindications dosages etc of these agents are covered in detail in another chapter (p 814) they will not be repeated here

In view of the nature of urinary tract infection it seems possible that prolonged treatment for from 2 weeks to several months might be ideal This however is impractical in many situations Nevertheless every effort should be made to administer the appropriate drug or drugs for 7 to 10 days no matter how prompt the symptomatic response may be It is essential to obtain follow up urine cultures 1 to 3 months after discontinuing of treatment to avoid overlooking smoldering asymptomatic infection with its potentialities for eventual development of serious disease It is probably unwise to employ catheter specimens for these follow up examinations since they may actually cause reinfection of the urinary tract and are not wholly reliable as methods of obtaining uncontaminated urine from the bladder With proper care it is possible to obtain suitable *clean voided specimens of urine from* females as well as males

Prognosis It is usually possible to obtain a dramatic cessation of symptoms in the treatment *of acute urinary tract infection not complicated by* other diseases The dangerous feature is the possible persistence of chronic asymptomatic infection which will gradually destroy the kidney or lead to development of hypertension (p 1319) It is not possible to state what the risk is that a simple cystitis may spread to one or both kidneys and it is often extremely difficult to decide whether infection is limited to the lower urinary tract Nevertheless the fact that a significant proportion of patients coming to autopsy show evidence of pyelonephritis and some degree of renal damage indicates the great importance of this problem In patients with some of the complicating diseases mentioned above particularly neurogenic bladder irremediable obstruction or multiple stones *eradication of urinary tract infection is exceedingly* difficult if not impossible Even here however it is usually possible to minimize the extent of the process by means of comprehensive care including surgical measures prevention of stone formation and appropriate chemotherapy guided by reliable laboratory procedures

145 BACTERIAL ENDOCARDITIS

Paul B Beeson

Bacterial endocarditis includes a variety of clinical syndromes some of which pursue a rapid and acute course whereas others evolve slowly over a period of many months By far the commonest type of bacterial endocarditis is the subacute variety caused by streptococci of the *viridans* group

liver When present these manifestations may dominate the clinical picture and may in fact obscure the diagnosis

The *manifestations of embolic phenomena* depend upon the tissues involved There may be hemiplegia meningeal inflammation infarction of lung myocardium mesentery spleen or kidney or occlusion of peripheral arteries In right sided endocarditis or patent ductus endarteritis emboli are carried to the lungs these may be responsible for an erroneous diagnosis of pneumonia

The *course* of subacute bacterial endocarditis is variable and may last from 1 month to 2 years Before effective methods of treatment were available the majority of patients died within 9 months of the onset

Intercurrent infections are not very common although bronchopneumonia occurs occasionally In rheumatic subjects the development of arthritis produces a clinical picture which may be indistinguishable from acute rheumatic fever

Since the introduction of penicillin therapy which controls the infection in most instances the principal *cause of death* in subacute bacterial endocarditis is progressive intractable cardiac decompensation This is probably the result of valvular damage which renders the heart mechanically less efficient together with myocarditis and increased demand for cardiac work occasioned by fever and anemia Some patients die following cerebral myocardial or mesenteric embolism while others succumb to a progressive "toxemia" of infection without localizing manifestations Rarely death is due to uremia caused by a progression of the nephritis this is more likely to occur in the relatively inactive cases Sometimes coma and death are the result of multiple small cerebral emboli which do not give localizing signs

Laboratory Findings The *leukocyte count* in the peripheral blood is usually moderately elevated but may be within the normal range *Circulating macrophages* may be found in smears of the peripheral blood These are thought by some hematologists to be of diagnostic value In cases of long standing a moderately severe normochromic *anemia* may be present There may be an *increase in serum globulin* and *cold precipitable globulins* are found in some cases The erythrocyte *sedimentation rate* is elevated Microscopic hematuria is very common and is helpful in diagnosis Albumin may also be found in the urine The *blood culture* is positive for *Streptococcus viridans* in about 80 per cent of cases In these cases the number of colonies of bacteria per milliliter of blood is usually approximately the same from day to day In a minority of instances the blood culture is consistently negative for reasons which are not clear It may be that in these cases the bacteria grow more deeply in the vegetations and hence do not have free access to the circulating blood It is often said that bacterial endocarditis located on the right side of the heart is more likely to be associated with negative blood cultures but there is little foundation for this assertion Actually it is not at all uncommon for bacteremia to be present in cases of right sided bacterial endocarditis

Differential Diagnosis The diagnosis of subacute bacterial endocarditis may be very easy or may be extremely difficult depending on the prominence of the various manifestations In a patient with the cardinal manifestations of fever heart murmur splenomegaly petechiae and clubbing of the fingers the diagnosis is obvious On the other hand subacute bacterial endocarditis can be a most difficult diagnostic problem since it can simulate a variety of diseases *The possibility of subacute bacterial endocarditis should be considered in every patient with fever and heart murmur* The diagnosis is missed most often in elderly patients especially those whose presenting complaint is the result of a cerebral embolic accident in such individuals a diagnosis of cerebral thrombosis or hemorrhage is likely to be made and little consideration given to the presence of a systolic murmur or low grade fever Heart murmur is so constantly present in the established disease (99 2 per cent of Kelson and White s series of 250 cases) that the diagnosis of subacute bacterial endocarditis can be excluded fairly safely in patients without murmurs An exception to this is the not infrequent absence of a murmur in early infections of the aortic valve in such cases a typical murmur may appear during treatment

This disease is one of the classic causes of "fever of undetermined origin" the important differential diagnostic points of which are covered elsewhere (p 72) Chief among the disorders which can be confused with it are systemic lupus erythematosus Hodgkin s disease miliary tuberculosis brucellosis periarteritis nodosa and acute rheumatic fever

Prognosis The natural course of the disease almost invariably leads to death the incidence of spontaneous recovery being less than 1 per cent In the past many forms of therapy were tried but found ineffective these included transfusions from immunized donors autogenous vaccines antiseptic drugs irradiation of the heart valves and so on With sulfonamide therapy a small proportion of patients probably not more than 4 per cent of those treated recovered The advent of antibiotic treatment brought about a great change in outlook and at present about 70 per cent of these *infections can* be brought under control Factors which point to

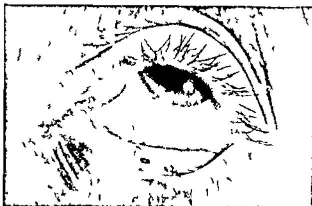

Fig 141 White centered conjunctival petechia in a patient with subacute bacterial endocarditis (*Courtesy Dr John Wedgwood Cambridge England*)

low pathogenicity and when separated from the protection of the vegetation they are readily de stroyed An exception should be made for cases in which enterococcus is the infecting organism since they may develop suppuration at sites of embolization especially in the spleen

The *myocardium* may be the site of a low grade inflammatory process which is probably an em bolic myocarditis The *spleen* is nearly always en larged and in most instances shows areas of in farction The *kidneys* which because of their rich blood supply constantly receive small emboli show changes of focal embolic nephritis In addition a diffuse glomerulitis is commonly encountered These processes may result in renal insufficiency which can be fatal

Manifestations In about one third of cases symp toms begin 1 to 3 weeks after some other illness such as acute respiratory infection or septic abor tion or some operative procedure such as dental extraction tonsillectomy or urethral instrumenta tion

The symptoms and course of subacute bacterial endocarditis do not conform to any single typical picture since they depend upon many factors in cluding the extent of the preexisting valve damage and the chance distribution of emboli The symp toms of congestive failure may be superimposed at any time during the course of the disease

In only about 25 per cent of cases is the onset of symptoms sufficiently dramatic that it can be recalled with certainty by the patient More often the illness begins very insidiously and the patient cannot name the exact time of onset The principal *symptoms* are weakness malaise feverishness chills (occasionally) sweating weight loss ano rexia nausea joint pains paresthesias and paraly sis

The patient usually appears chronically ill The skin is pale and sometimes has a tan color the so called *café au lait* appearance The skin may be flushed and hot or it may be wet with perspiration Tiny *petechial hemorrhages* may be visible in any part of the body they are particularly evident on mucosal surfaces the conjunctiva the palate or the buccal mucosa Some of the petechiae in the conjunctiva have white or gray centers (see Fig 141) these are considered by many to be of diag nostic significance but are occasionally seen in other conditions A distinctive lesion can sometimes be seen in the ocular fundus—the Roth spot" This consists of a circular or oval pale area surrounded by a ring of hemorrhage usually near the disk (Similar lesions occur in acute myelogenous leu kemia and in septicemia) Petechiae may be found on any area of the skin they have to be distin guished from other lesions such as small angiomas The latter usually blanch when pressed with a glass slide It is sometimes helpful to circle all suspicious lesions with ink and reexamine them later Old petechiae fade in a day or two and new ones appear in other areas whereas angiomas do not change Petechial hemorrhages in the nail beds usually are located near the distal margin and have a linear shape resembling embedded splinters hence the name *splinter hemorrhages* Small pain ful reddish or purplish areas in the pulps of the fingers (*Oslers nodes*) may develop during the course of the disease they usually disappear within a day or two Larger painful erythematous areas may appear from time to time on the palms of the hands or soles of the feet Embolization of small arteries in the digits or in the nose occasionally produces a local area of gangrene In cases of long duration *clubbing of the fingers* is likely to be present Examination of the heart reveals the signs of the preexisting valvular defect Changing mur murs have often been mentioned as helpful in diag nosis but too much stress should not be given this sign The changes which do occur are most often due to the circulatory effect of anemia and fever Occasionally however there are rather striking fluctuations these are especially likely to occur in patent ductus endarteritis The *spleen* is palpable in more than one half of all cases following an in farction there may be severe pain and tenderness in the left upper quadrant and a friction rub may be audible over the left lower costal margin Inflam mation of *joints* occurs in about one fourth of all cases and may simulate acute rheumatic fever The pathogenesis of these arthritides is not clear

Symptoms and signs of congestive heart failure may be present from the onset or may appear at any time during the course of subacute bacterial endocarditis There may be orthopnea distention of the neck veins peripheral edema rales in the lungs pleural effusion and a large tender swollen

liver When present these manifestations may dominate the clinical picture and may in fact obscure the diagnosis

The *manifestations of embolic phenomena* depend upon the tissues involved There may be hemiplegia meningeal inflammation infarction of lung myocardium mesentery spleen or kidney or *occlusion of peripheral arteries In right sided endocarditis* or patent ductus endarteritis emboli are carried to the lungs these may be responsible for an erroneous diagnosis of pneumonia

The *course* of subacute bacterial endocarditis is variable and may last from 1 month to 2 years Before effective methods of treatment were available the majority of patients died within 9 months of the onset

Differential Diagnosis The diagnosis of subacute bacterial endocarditis may be very easy or may be extremely difficult depending on the prominence of the various manifestations In a patient with the cardinal manifestations of fever heart murmur splenomegaly petechiae and clubbing of the fingers the diagnosis is obvious On the other hand subacute bacterial endocarditis can be a most difficult diagnostic problem since it can simulate a variety of diseases *The possibility of subacute bacterial endocarditis should be considered in every patient with fever and heart murmur* The diagnosis is missed most often in elderly patients especially those whose presenting complaint is the result of a cerebral embolic accident in such individuals a diagnosis of cerebral thrombosis or hemorrhage is likely to be made and little consideration given to the presence of a systolic murmur or low grade fever Heart murmur is so constantly present in the established disease (99.2 per cent of Kelson and White s series of 250 cases) that the diagnosis of subacute bacterial endocarditis can be excluded fairly safely in patients without murmurs An exception to this is the not infrequent absence of a murmur in early infections of the aortic valve in such cases a typical murmur may appear during treatment

This disease is one of the classic causes of "fever of undetermined origin " the important differential diagnostic points of which are covered elsewhere (p 72) Chief among the disorders which can be confused with it are systemic lupus erythematosus Hodgkin s disease miliary tuberculos s brucellosis periarteritis nodosa and acute rheumatic fever

Prognosis The natural course of the disease almost invariably leads to death the incidence of spontaneous recovery being less than 1 per cent In the past many forms of therapy were tried but found ineffective these included transfusions from immunized donors autogenous vaccines antiseptic drugs irradiation of the heart valves and so on With sulfonamide therapy a small proportion of patients probably not more than 4 per cent of those treated recovered The advent of antibiotic treatment brought about a great change in outlook and at present about 70 per cent of these infections can be brought under control Factors which point to

a favorable outcome in order of importance are penicillin sensitive organism freedom from signs of heart failure positive blood culture and short duration of illness

Treatment The following general statements deserve emphasis

1 Eradication of the infection requires employment of chemotherapeutic agents which exert a bactericidal action presumably because in their protected location the organisms must be killed without the aid of phagocytosis

2 Penicillin is the antibiotic of prime importance The special properties which make it so valuable in this situation are that huge doses can be tolerated by man that it diffuses into the vegetation in high concentration that organisms do not rapidly develop resistance to it and most important of all that it can be bactericidal and can eradicate the causative organisms without aid of phagocytes With most other antibiotics the situation is less favorable Even though capable of inhibiting bacterial growth in vitro the bacteriostatic antibiotics such as the tetracyclines and chloramphenicol rarely achieve a cure in this infection Therefore even when sensitivity tests indicate that the organism is as sensitive or even more sensitive to some other antibiotic penicillin may be the only agent capable of eliminating the infection

3 Streptomycin almost worthless when used alone has a place in treatment as an adjunct to penicillin This pertains especially to infections due to enterococcus which is relatively resistant to penicillin alone In the case of other varieties of *S viridans* the value of the combination therapy is less certainly established but since it may be beneficial and almost certainly does not detract from the efficacy of penicillin current practice in most places is to use both drugs in all cases of *S viridans* endocarditis

4 In an occasional case either because the organism is totally unaffected by penicillin (and streptomycin) or because the patient is so allergic to penicillin that this therapy in itself would threaten his life some other antibiotic regimen has to be employed Sensitivity tests with various combinations of antibiotics with special attention to bactericidal effect must be employed Bacitracin and neomycin despite the greater risk of toxic reaction are likely to be preferable to chloramphenicol or the tetracyclines Erythromycin and novobiocin may be effective especially when combined with other drugs

5 Antibiotic treatment must be continued for a considerable period of time In early experience with penicillin the impression was formed that treatment had to be maintained for 6 to 8 weeks and some authorities still regard this as the safest practice in all cases However later experience based upon use of much larger daily doses of penicillin in combination with streptomycin indicates that courses of treatment of 2 to 4 weeks are sufficient in most instances These shorter courses are justified in cases where the duration of illness is less than 3 months the organism is sensitive to penicillin and where there is prompt clinical improvement following the beginning of treatment Without these favorable indications it is safest to continue treatment for up to 8 weeks

Since the diagnosis can often be made with reasonable certainty on clinical grounds before bacteremia can be demonstrated and since in perhaps 20 per cent of cases blood cultures remain negative the question which often arises is how soon to begin chemotherapy An accurate bacteriologic diagnosis including antibiotic sensitivities is of great value and should be achieved if possible but undue delay of treatment must be avoided because of the possibility of embolic accident and progressive destruction of a cardiac valve A reasonable practice is to collect 4 to 6 blood cultures during a 48 hr period then begin treatment with penicillin and streptomycin observing the clinical response and modifying the chemotherapeutic regimen later as dictated by bacteriologic findings

When the infecting organism is penicillin sensitive a suitable dosage schedule is 2 400 000 units penicillin and 1 Gm streptomycin per day If the clinical response is not satisfactory or if the organism is only slightly sensitive to penicillin very much larger doses of penicillin up to 100 000 000 units per day may have to be given The dosage of streptomycin probably should seldom exceed 2 Gm per day The administration of very large amounts of penicillin is technically difficult since the pain of intramuscular injections is often severe and their intravenous administration may cause chemical phlebitis In order to maintain such a program of treatment for several weeks it is usually necessary to employ a variety of methods including continuous and intermittent intravenous and intramuscular injections Adjuvants such as Benemid may be used to reduce the rate of excretion of penicillin by the kidneys Ingenuity technical skill and stubborn persistence on the part of the doctor may be life saving

Embolic accidents resulting in hemiplegia mesenteric infarction or occlusion of a peripheral artery may take place many days after the beginning of effective antimicrobial therapy

The course of the fever after beginning chemotherapy is somewhat variable In most instances there is a defervescence within the first day or two but sometimes even when the end result is satisfactory a low grade fever continues for as long as 2 or 3 weeks

The treatment of congestive heart failure in bac

terial endocarditis does not differ from that of other kinds of congestive heart failure (see p 1304)

In infections located on patent ductus arteriosus or arteriovenous fistula cure can sometimes be achieved by surgical excision or obliteration of the fistulous tract Such operative treatment can be carried out during or at the conclusion of an appropriate course of chemotherapy

Relapse may occur after the cessation of penicillin therapy especially when the period of treatment has been short The great majority of relapses occur within the first 4 weeks after cessation of treatment It is usually safe to consider a patient s infection eradicated if he is free of symptoms and signs of the disease and if his blood cultures show no growth 6 weeks after the conclusion of therapy A recrudescence after that time may be due to a new infection rather than to persistence of the initial one

In the event of relapse additional chemotherapy is indicated It is particularly important to check the sensitivity of the infecting organism and to adjust the dose of penicillin or other antibiotic accordingly

Persons who have recovered from subacute bacterial endocarditis should be given prophylactic penicillin therapy before any operative procedure in an infected area such as tonsillectomy or tooth extraction It is advisable to administer penicillin orally in a dosage of one million units daily for 2 days prior to the procedure and for one day afterward

OTHER ETIOLOGIC AGENTS IN BACTERIAL ENDOCARDITIS

Although streptococci of the *viridans* type are by far the commonest cause of bacterial endocarditis accounting for approximately 90 per cent of all cases a wide variety of other microorganisms may be the cause of subacute or acute bacterial endocarditis These include nonpathogenic bacteria such as *S albus Hemophilus parainfluenzae* which give rise to the subacute pattern of disease just described and many genuinely pathogenic organisms such as *S aureus S pyogenes Brucella* the gonococcus meningococcus and pneumococcus which are likely to give a more fulminating disease picture In addition to bacteria certain of the fungi such as *Histoplasma capsulatum* have been shown to cause bacterial endocarditis

The term *acute bacterial endocarditis* is usually given to those cases in which the etiologic organism is a true pathogen such as *S aureus* or the pneumococcus and in which the course is relatively rapid—i e a few weeks This type of infection may involve previously normal valves hence a heart murmur may not always be present at the onset of illness The clinical picture is characterized not only by a short course but also by high fever multiple petechial hemorrhages and other embolic manifestations development of metastatic abscesses in other parts of the body and rapid destruction of the heart valve

The results of chemotherapy in these fulminating infections are still unsatisfactory Probably not more than 20 per cent of patients with acute staphylococcal or pneumococcal endocarditis recover even though the organism may appear to be sensitive to penicillin in the test tube Autopsies often reveal healing of the ulcerative endocarditis but the presence and persistence of one or more abscesses elsewhere Especially noteworthy are myocardial abscesses located in the region of the valve ring Apparently the sterilization of infection in such an abscess is very difficult to achieve with chemotherapy and this seems to be one of the reasons for the poor results obtained in this disease

146 PYOGENIC INFECTIONS OF THE NERVOUS SYSTEM

John N Walton

Since many of the infective disorders of the central nervous system have already been dealt with elsewhere this chapter will be limited to a discussion of specific neurologic syndromes which arise when pyogenic bacteria or their products encroach upon nervous tissue It is proposed to consider the neurologic effects of suppuration within the cranial cavity or vertebral canal and to mention briefly certain particular neurologic aspects and complications of meningitis

Pyogenic organisms may gain access to the cranial cavity or spinal canal in a number of ways So far as the cranium is concerned direct spread of an infective process beginning in the middle ear or in

a paranasal sinus may give an osteomyelitis of cranial bones This in turn will often affect the extradural space whence further spread is possible through the meninges to the brain itself Septic thrombosis of diploic and emissary veins may play an important part in the process In the vertebral column osteomyelitis of a vertebra may play a similar role The next most frequent source of suppuration around or within the neuraxis is metastatic infection with blood borne organisms arising from a remote septic focus often in the skin or lung Lymphatic spread from a nearby locus of infection may account for certain cases of intraspinal suppuration but is virtually unknown as a cause of intracranial abscess formation In other cases organisms may be introduced by foreign bodies such as projectiles while rarely faulty aseptic technique in such procedures as lumbar puncture o cranial exploration may be responsible Of all the mechanisms described direct spread from the enveloping bony cage and metastatic infection are by far the most common in civilian medical practice

NEUROLOGIC ASPECTS OF BACTERIAL MENINGITIS

Bacterial meningitis as typified by that due to the meningococcus is regarded by many as a disease in which the pathologic changes are limited to the subarachnoid space and do not encroach upon nervous tissue It is also generally believed that these changes are entirely reversible with adequate treatment While both these views have considerable substance it is also true that sometimes lasting disability or a fatal outcome is due not to the meningitis but to certain distinctive pathologic changes which the disease produces in the nervous parenchyma Indeed it is probable that such changes may be far more frequent than is generally realized Similarly certain other neurologic manifestations are now known to depend upon vascular changes which are a part of the inflammatory process while others as well as some common sequelae may be attributed to incomplete resolution of the meningeal inflammation

Having accepted these generalizations it is possible to say that modern antibiotic and chemotherapeutic methods of treatment have greatly reduced the incidence of complications particularly in meningococcal meningitis However they are still of considerable importance in the other forms which show a less uniformly favorable response to treatment In tuberculous meningitis they are an outstanding feature

It is perhaps justifiable to consider the pathologic findings in fatal cases of influenzal meningitis as typifying the changes observed There are wide variations in the pathologic picture which can probably be related in most cases to the duration of the illness but in others are dependent on numerous factors particularly the resistance of the patient and the efficacy of treatment

The outstanding changes may be classified as follows

1 Subdural effusions serous or purulent
2 Severe brain swelling with tentorial or cerebellar herniation
3 Acute hydrocephalus without blockage of cerebrospinal fluid pathways
4 Ischemic necrosis of cerebral cortex or in more chronic cases nerve cell degeneration with marked glial reaction
5 Subependymal perivascular cellular infiltration with astrocytic and microglial proliferation
6 Subpial degeneration of spinal cord superficial as well as irregular parenchymatous degeneration of cranial and spinal nerves
7 Vascular changes
   a Cortical thrombophlebitis
   b Endothelial swelling and cellular infiltration in meningeal arteries in some cases there is a severe arteritis leading to thrombosis
8 Organization of exudate with meningeal fibrosis

Subdural empyema is a relatively uncommon complication of bacterial meningitis and will be considered in detail shortly ***Serous subdural effusions*** have been recognized recently as an important complication of meningitis in infancy McKay Ingraham and Matson found such collections in 60 per cent of all patients under 1 year of age who were suffering from meningococcal influenzal or pneumococcal meningitis They suspect that such collections may be present if any of the following features are noted (1) persistent high temperature after 72 hr of adequate treatment (2) positive cerebrospinal fluid culture after 48 hr of treatment (3) convulsions during convalescence (4) focal convulsions at any time (5) vomiting during the convalescent period (6) gross neurologic abnormality (7) clinical impression that the course is unsatisfactory Any one of these findings is they believe an indication for aspiration of the subdural space carried out by needling in the lateral angle of the anterior fontanel If a subdural effusion is present fluid will readily be withdrawn It is always xanthochromic and may even be frankly bloody it usually contains up to 2 or 3 Gm per 100 ml of protein and several hundred white cells per cubic millimeter It is sterile on culture in most cases Many workers believe that this complication is best treated by daily aspiration while antimicrobial therapy is continued Others however suggest that in these patients a subdural membrane similar to that of chronic subdural hematoma is

present and should be removed surgically McKay Ingraham and Matson believe that if such a mem brane is left it will interfere with the growth of the brain In the absence of any conclusive evidence that this does in fact occur it seems that repeated aspiration is the treatment of choice and that surgery should be reserved for those cases which fail to respond to this regimen

In a proportion of the cases of acute meningitis which die within 24 to 48 hr of the onset an *acute brain swelling* or alternatively *hydrocephalus* may be seen producing fatal tentorial or cerebellar herniation The exact cause of these changes is un known though they seem to be related in some way to the acuteness of the disease process

The etiology of the cortical and subependymal changes is also obscure The diffuse nerve cell de generation and subpial glial reaction are probably evidence of a *noninfectious encephalomyelopathy* due to a number of circulatory and toxic factors but the subependymal changes may be the result of direct bacterial invasion This encephalopathy is probably responsible for the stupor coma and the generalized convulsions of the disease The areas of *cortical necrosis* probably explain many of the focal neurologic symptoms and signs such as focal sei zures or hemiplegia Pain in the limbs blindness and deafness or other cranial nerve palsies can be attributed to *degenerative changes in the nerves or roots* Chronic meningeal fibrosis so-called *ad hesive arachnoiditis* may sometimes produce simi lar effects as a late sequel through constriction of nerve trunks

The *arterial infiltration* already described does not appear to be responsible for important nervous lesions in pyogenic meningitis *Thrombophlebitis* may give rise to focal convulsions neurologic signs or subarachnoid bleeding through cortical infarc tion The thrombophlebitis is generally aseptic and occasionally involves the sagittal sinus giving a syndrome which will be discussed later in this chapter

Meningeal fibrosis and organization of exudate can block the aqueduct the foramens in the roof of the fourth ventricle or the tentorial hiatus Ob structive or communicating hydrocephalus results Similar dense meningeal thickening around the brain stem may sometimes be responsible for the tonic spasms which occasionally accompany and follow meningitis and it is conceivable that they may even be the basis for the terminal decere brate state of some such patients

Although these changes have been most care fully studied in influenzal and pneumococcal men ingitis it is probable that the complications and sequelae of most forms including tuberculous meningitis are similarly determined Tuberculosis may be complicated by infarction due to arterial occlusion since the basal arteritis which has been well described by Doniach is more striking in this than in other types of meningitis

INTRACRANIAL SUPPURATIVE DISORDERS

If bacterial meningitis is excluded it can be said that suppurative disease within the cranial cavity occurs in one of five situations The process may occur external to the dura in which case an *extra dural abscess* results or it may penetrate the dura to give a *subdural abscess* or *empyema* very rarely a localized *subarachnoid abscess* may occur within the subarachnoid space In other instances the in flammation may affect principally an intracranial venous sinus or its radicals giving *suppurative thrombophlebitis* Most commonly of all the inflam matory process involves brain tissue beginning as a diffuse process of *suppurative encephalitis* This inflammatory process may continue to spread until the patient dies but more often the infected area or areas become surrounded by reactive tissue to give one or more *brain abscesses*

Practically all extradural and subdural abscesses and more than 50 per cent of brain abscesses are produced by centripetal spread of suppuration from the cranial bones

Extradural Abscess

The cranial osteomyelitis responsible for produc ing an extradural abscess is generally due to otitis media sinusitis or trauma Pus accumulates on the inner side of the cranium and strips off the dura which becomes lined on its external surface by a layer of granulation tissue An abscess in this situa tion is difficult to diagnose since it is rarely large enough to produce a severe increase in intracranial pressure or focal neurologic signs It may however be suspected in the presence of irregular pyrexia and headache which radiates from either the mas toid (in otitis media) or frontal region (in frontal sinusitis) there is often marked tenderness of the skull in the affected region The cerebrospinal fluid may be normal but usually shows a slight poly morphonuclear or mononuclear pleocytosis This condition can be treated effectively by antibiotic therapy and surgical drainage

Subdural Abscess or Empyema

This syndrome is usually a complication of frontal sinusitis it sometimes occurs in otitis but is rarely metastatic

In most cases infection of the subdural space is effected by direct extension through the dura but in others it is the result of septic thrombophlebitis of venous sinuses particularly the superior longi tudinal The subdural pus usually covers the greater part of the lateral surface of the affected hemisphere

and tends to accumulate over the lateral aspect of the frontal lobe In fatal cases ischemic necrosis of subjacent cortical gray matter is found and thrombosis of subarachnoid and cortical veins is frequent

The symptomatology of this disease follows a relatively stereotyped pattern When it complicates sinusitis there is usually exacerbation of frontal pain and nasal discharge followed by orbital swelling headache is at first localized to the frontal region but later becomes generalized and increases in severity Concurrently high fever neck stiffness and drowsiness or stupor develop and are followed by focal neurologic signs Jacksonian seizures are common aphasia is seen in left sided lesions paralysis of contralateral ocular deviation is frequent and all patients have a *hemiparesis* or *hemiplegia* Clinical manifestations in cases not caused by sinusitis are identical save for the absence of signs of sinus infection and orbital swelling

Most cases show a marked increase in cerebrospinal fluid pressure and the total protein content is raised often to about 100 mg per 100 ml though the sugar remains normal and the fluid is sterile on culture A cell count of several hundred per cubic millimeter is usual and the majority of the cells are *polymorphonuclear leukocytes*

If not treated the condition is fatal within about 10 to 14 days after the onset of headache or 3 to 4 days after the accession of focal neurologic signs Effective treatment consists in administration of the appropriate antibiotic combined with drainage of the abscess through one or more burr holes Attempts to drain the abscess through the frontal sinuses or ear almost invariably fail

It is sometimes difficult to distinguish this condition from intracranial thrombophlebitis or from necrotizing encephalopathy with predominant involvement of one hemisphere

Intracranial Thrombophlebitis

This most often affects the lateral cavernous or superior longitudinal sinuses owing to centripetal spread of infection from the middle ear the skin of the face or the frontal sinus respectively In all three conditions the patients are acutely ill with high remittent fever

In *lateral sinus thrombosis* there is usually headache in the temporal region Papilledema may sometimes occur but focal neurologic signs are generally absent and the clinical picture is dominated by the manifestations of pyemia Compression of the homolateral internal jugular vein may produce no rise in pressure during spinal manometry whereas a normal rise occurs during compression on the opposite side (Tobey Ayer test)

Cavernous sinus thrombosis gives homolateral frontal headache and facial pain followed by proptosis edema of the eyelids chemosis and paresis of oculomotor nerves Often the infection spreads through the circular sinus to the other cavernous sinus This may sometimes be prevented by early treatment

Suppuration within the *superior longitudinal sinus* usually produces headache and marked papilledema with edema and engorgement of the scalp over the vertex A monoplegia of one leg or a paraplegia may result from infarction of the leg area or areas of the motor cortex but this is uncommon More often a subdural empyema results

Septic thrombosis in any of the three situations requires vigorous chemotherapy and this is the only method of treatment in cavernous sinus disease Surgical exposure and drainage of the lateral sinus or ligation of the internal jugular vein may sometimes be required

Aseptic thrombosis of intracranial venous sinuses particularly the lateral and superior longitudinal is an occasional complication of otitis media and in many such cases there is no evidence of intracranial spread of microorganisms The resulting syndrome is characterized by severe papilledema and increase in the intracranial pressure with comparatively little headache it has been called *otitic hydrocephalus* by Symonds In severe cases (when the process extends to cortical veins) seizures focal neurologic signs and even profuse subarachnoid hemorrhage may result from cortical infarction An identical syndrome not uncommonly occurs in marasmic infants in cachectic patients during pregnancy following closed head injury or in individuals with heart disease or blood dyscrasias

Brain Abscess

Incidence Brain abscess may occur at any age and is equally common in the two sexes It is probable that fewer cases of otitis and intrathoracic suppuration have been complicated in this way since the advent of antibiotic therapy but certain patients who would previously have died from the primary infection now survive to develop a brain abscess

Etiology and Location About 40 per cent of brain abscesses are secondary to middle ear disease and of these about a third arise in the anterior part of the lateral cerebellar lobe the remainder lying in the middle part of the temporal lobe above the tegmen tympani Frontal sinusitis accounts for roughly 10 per cent of cases and the abscess is almost invariably situated in the anterior part of the frontal lobe Of the remaining 50 per cent of cases a small proportion are due to penetrating wounds and the remainder are metastatic in about half of these the primary septic focus is in the lung (bronchiectasis empyema lung abscess) and in

the others it may be in the skin or other diverse locations such as bone or the heart Brain abscesses are particularly frequent in patients with congestive heart failure or cyanotic congenital heart disease even without evidence of bacterial endocarditis In traumatic cases the site of the abscess will clearly depend upon the area which has been traumatized but a metastatic abscess may be situated anywhere within the cranium though it is usually above the tentorium Most lie within the distribution of the middle cerebral artery beginning at the junction of the gray and white matter they are not infrequently multiple or multiloculated a finding which is less frequent in the case of otitic abscesses

Almost any of the common organisms may cause a cerebral abscess the most frequent being streptococci pneumococci and staphylococci while fusiform bacilli and oral spirochetes are sometimes found Less commonly such organisms as *Endamoeba coli Actinomyces* or even *E histolytica* may be responsible

Pathology Invasion of nervous tissue by the causal organism leads initially to focal necrosis and liquefaction accompanied by edema of the surrounding brain this stage is called *suppurative encephalitis* If the patient survives pus accumulates and a capsule begins to form from fibroblasts derived from proliferating capillaries In due course a firm thick fibrous capsule forms and may be several millimeters in diameter it is lined by a layer of granulation tissue containing polymorphonuclear leukocytes histiocytes lymphocytes and proliferating capillaries In brain tissue surrounding the fibrous wall are found reacting microglia fibroblasts and astrocytes in profusion

Clinical Manifestations The physician should be aware of the many ways in which a brain abscess may develop for early diagnosis is the key to effective treatment Early in the illness the patient s symptoms are all important since physical signs may not develop until a relatively late stage When a known sufferer from otitis media experiences a suppression of aural discharge following a period of exacerbation and this is succeeded by headache vomiting and confusion it is reasonable to suspect that inflammation has spread intracranially In many cases however the symptoms are not striking and the patient may seem to recover from a flare up of his otitis but remains unwell experiencing attacks of depression and irritability vague intermittent headache and nausea anorexia weight loss and mild fever Symptoms and signs of meningeal irritation are usually minimal A history of this type in a patient with paranasal sinusitis should also make one suspicious of intracranial suppuration the cerebrospinal fluid should be examined immediately

In hematogenous abscess the onset is sometimes dramatic with sudden focal seizures and neurologic signs followed after an interval of days or weeks by increasing pyrexia and evidence of mounting intracranial pressure This may be seen when an infected embolus becomes impacted in a large vessel Far more often however the onset is insidious with minimal headache slight intermittent pyrexia and gradual personality change When there is an evident septic focus in the skin or lung the possibility of abscess may spring to mind but in many other instances the patient may be felt to be suffering from an intracranial tumor This is particularly common when antibiotic therapy effectively masks the patient s symptoms throughout the stage of suppurative encephalitis

When the clinical manifestations of brain abscess are more fully developed they fall into three groups (1) general symptoms of infection (2) symptoms and signs of increased intracranial pressure and (3) focal symptoms and signs

The severity of the *general symptoms of infection* is related to the acuteness of the disease process In cases of acute suppurative encephalitis they may be severe in patients in whom the onset is more insidious a low intermittent pyrexia is the rule while in more chronic cases the temperature may be normal throughout

Some evidence of *increased intracranial pressure* is usually found although in a few patients with large chronic abscesses it may be lacking In general the patients have headache which may occasionally be localized over the area of suppuration More often it is of the type usually seen in increased intracranial pressure being paroxysmal worse in the mornings and increased by movement Nausea is frequent and is followed by vomiting in the later stages The pulse is more likely to be slow in patients with abscess than in any other form of intracranial disease Papilledema is usually a late sign but mental changes consisting of mild confusion and irritability or other change in temperament progressing to severe confusion drowsiness stupor and coma are commonly present

Temporal Lobe Abscess If the abscess affects the dominant hemisphere dysphasia which is often of nominal" or "amnesic type is frequent the patient finds difficulty in naming familiar objects A homonymous upper quadrantic field defect is often seen because of involvement of the optic radiation Evidence of pyramidal tract involvement is usually minimal and may be little more than slight contralateral facial or finger weakness though extensive lesions may give a hemiparesis Herniation of the temporal lobe through the *tentorial hiatus* may lead to a homolateral third nerve palsy to

coma and to signs of bilateral disease of the pyramidal tracts.

Cerebellar Abscess. Headache in the suboccipital region is common, and the neck may be stiff or held to one side. Evidence of increased intracranial pressure is often more striking in these patients than in those with abscesses situated elsewhere. Signs of cerebellar deficiency such as hypotonia, incoordination, past pointing, and slow performance of rapid alternating movements may be seen in the limbs on the affected side. The patient may tend to fall or stagger to this side on walking. Nystagmus is usually present, being most marked on lateral gaze to the side of the lesion; there may also be compression of the brain stem leading to cranial nerve pareses and contralateral pyramidal signs, but these manifestations are most variable. Homolateral pyramidal signs may occur, due probably to compression of the contralateral cerebral peduncle against the free edge of the tentorium.

Frontal Lobe Abscess. Patients with frontal lobe abscess often show no focal neurologic signs. Headache, drowsiness, and impairment of memory, attention, and intellectual function are prominent. In some cases there is a grasp reflex and contralateral deviation of the head and eyes. If the abscess is large, a hemiparesis and dysphasia (in dominant hemisphere lesions) may result.

Diagnostic Procedures. Examination of the *cerebrospinal fluid* may be of great diagnostic value, but this procedure should be carried out with care, particularly in those cases in which a temporal or cerebellar abscess is suspected. In such a case, removal of even a moderate quantity of fluid can lead *to herniation of the temporal lobe through the* tentorial hiatus or of the cerebellum through the foramen magnum with fatal results. Whenever there is evidence of increased intracranial pressure, only a small amount of fluid should be removed, and in the presence of marked papilledema the procedure is contraindicated. The fluid usually shows an increased pressure, and its protein content is often higher than 100 mg per 100 ml; it rarely contains more than 100 white cells per cubic millimeter, and the majority are mononuclear, though a number of neutrophils may be present in the early stages. The sugar content of the fluid is normal, and no bacteria are seen in smears or isolated by culture. *Electroencephalography* may be of considerable value in diagnosis and localization, since an abscess in one cerebral hemisphere usually gives a focus of extremely slow and irregular delta activity of high amplitude. *Radiography* of the skull may show displacement of the pineal body. *Angiography* may localize it accurately, but many surgeons prefer *ventriculography*. *Air encephalography* by the lumbar route is dangerous when the intracranial pressure is raised. After treatment of the abscess, instillation of Thorotrast into the cavity may demonstrate its progressive decrease in size.

Diagnosis. In the chronic abscess with no clear primary focus of infection, differentiation from intracranial tumor may be impossible except by cerebrospinal fluid examination or exploration. In the more acute cases, the condition is distinguished from meningitis by the absence of meningeal irritation and by the cerebrospinal fluid changes. In patients with otitis media there may be confusion between temporal abscess and lateral sinus thrombosis, or between cerebellar abscess and labyrinthitis. However, septic thrombosis of the lateral sinus is usually a more dramatic febrile illness than temporal abscess and rarely produces focal neurologic signs; in a proportion of cases the Tobey-Ayer manometric test will be positive. Labyrinthitis can usually be recognized, since it tends to give more vertigo and less headache than does cerebellar abscess and does not produce papilledema or changes in the cerebrospinal fluid.

Prognosis. Without treatment, brain abscess is an almost uniformly fatal disease save for the very rare cases which become quiescent and thickly encapsulated and a few in which spontaneous drainage occurs via the middle ear or frontal sinus. Death usually results from diffuse suppurative encephalitis, increased intracranial pressure, brain herniation, or from rupture of the abscess into the ventricular system or subarachnoid space. Before the days of antibiotics about 50 per cent of patients died despite surgical treatment; after penicillin became freely available, the mortality rate *dropped to under 30 per cent.*

Late Prognosis. Not all the 70 per cent of patients who survive after treatment of a brain abscess recover completely. Some are left with signs of neurologic deficit, varying from a mild field defect to hemiplegia. Recurrent headaches, intellectual impairment, and anxiety states are common, and about 50 per cent of surviving patients develop seizures as a sequel.

Treatment. During the stage of acute suppurative encephalitis, to carry out an intracranial operation is to court disaster through wider dissemination of the inflammatory process. In this stage every attempt should be made to isolate the responsible organism from either the cerebrospinal fluid or the primary septic focus. Vigorous antibiotic therapy with the appropriate agent, systemically and if possible intrathecally, is indicated. Sometimes a patient who appears to have all the typical symptoms and signs of a brain abscess recovers on medical therapy alone. The great majority, however, require surgical intervention. Occasionally in the presence of deepening coma and progressive neuro

logic signs operation may be necessary even in the acute stage More often it is possible to wait until the inflammatory process has become localized All abscesses presenting in the chronic stage should be operated upon promptly Details of surgical treatment are beyond the scope of this volume but it can be said that some surgeons prefer to aspirate the abscess and instill antibiotics while others believe in its total extirpation In the former method *it is easy to overlook multiple abscesses or separate* loculi and recurrences are possible but extirpation may leave more severe sequelae than would have occurred after aspiration Both methods have proved successful in the hands of their proponents

INTRASPINAL SUPPURATIVE DISORDERS

Of the suppurative conditions within the spinal canal epidural abscess is the commonest by far Very rarely an abscess may form within the subdural space following a penetrating wound or localization of a purulent meningitis however its clinical manifestations do not differ significantly from those of epidural abscess and in both conditions surgical exploration is required *Intramedullary spinal abscess* is also extremely rare it is almost invariably metastatic in origin tends to run a more rapid course than most cases of epidural suppuration and is attended by less pain than is the latter It often presents with paresthesias in the lower limbs followed by progressive flaccid paralysis Many cases of this type cannot be distinguished from other forms of acutely progressive myelopathy and few are diagnosed during life Foley has pointed out that the diagnosis may be suspected when clinical manometric and radiologic findings suggest an intramedullary tumor and there is also a clear focus of infection elsewhere in the body In such cases improvement and certainly survival may follow aspiration or incision and drainage of the abscess together with antibiotic therapy In view of the rarity of subdural and intramedullary suppuration in the spinal canal they will not be considered further Nor will tuberculous epidural abscess be given separate consideration since its presentation *and management are best considered* along with tuberculous spinal disease

Spinal Epidural Abscess

The recognition of this condition is a matter of paramount importance since surgical intervention in the early stages is usually rewarded by total recovery whereas even brief delay may lead to paraplegia quadriplegia or death There are few disorders in which early diagnosis is so imperative and for this reason alone it merits detailed description

Etiology Vertebral osteomyelitis is the cause of this syndrome in about a third of cases Hematogenous spread from an infective focus often cutaneous sepsis and sometimes pyelonephritis are presumably responsible for most of the remaining cases Much more rarely the abscess may arise through lymphatic spread from a paraspinous lesion such as mediastinal or retropharyngeal abscess and it is also possible for it to be caused by direct inoculation (lumbar puncture needle) or by a penetrating wound Almost invariably *Staphylococcus aureus* is the responsible organism

Pathology Granulomatous tissue with a variable amount of pus tends to accumulate in the epidural fat over the dorsal aspect of the dura and to spread longitudinally In osteomyelitic *cases aggregations* of purulent material are often found in the lateral epidural regions in relation to the bony lesion but an anterior accumulation is rare owing to the intimate relationship of the dura and the intervertebral ligaments Large collections of pus *are uncommon* more often it is found as multiple small pockets in exuberant granulation tissue The inflammatory process may extend axially so as to overlie as many as seven bony segments but is usually limited to three or four extension is less marked in the osteomyelitic cases The inflammatory process may also spread laterally and dorsally to involve paravertebral structures spinal muscles and even subcutaneous tissue but anterior extension is virtually unknown Nor does the process often traverse the dura its effect upon the spinal cord seems to depend upon a combination of a simple compression and interference with the circulation *in epidural* veins leading to derangement of the medullary circulation

Clinical Manifestations Heusner has pointed out that although spinal epidural sepsis produces clinical syndromes which differ in tempo there is a basic clinical pattern common to all variants It consists of the following march of events

Phase I Spinal ache
Phase II Root pain
Phase III Weakness of { voluntary muscles / sphincters / sensibilities }
Phase IV Paralysis

Sometimes the symptoms and signs of severe *infection* may partially mask the above features but they are always present if looked for with care The initial aching pain is usually accompanied by fever and the *spine is tender in the affected region* Within 2 or 3 days root pains are added which radiate from the affected segment and the spine is then exquisitely tender If the *condition* remains untreated the general signs of infection *increase* the spinal ache *becomes* excruciating neck stiffness develops and soon afterwards weakness *ascending*

coma and to signs of bilateral disease of the pyramidal tracts

Cerebellar Abscess Headache in the suboccipital region is common and the neck may be stiff or held to one side Evidence of increased intracranial pressure is often more striking in these patients than in those with abscesses situated elsewhere Signs of cerebellar deficiency such as hypotonia incoordination past pointing and slow performance of rapid alternating movements may be seen in the limbs on the affected side The patient may tend to fall or stagger to this side on walking Nystagmus is usually present being most marked on lateral gaze to the side of the lesion there may also be compression of the brain stem leading to cranial nerve pareses and contralateral pyramidal signs but these manifestations are most variable Homolateral pyramidal signs may occur due probably to compression of the contralateral cerebral peduncle against the free edge of the tentorium

Frontal Lobe Abscess Patients with frontal lobe abscess often show no focal neurologic signs Headache drowsiness and impairment of memory attention and intellectual function are prominent In some cases there is a grasp reflex and contralateral deviation of the head and eyes If the abscess is large a hemiparesis and dysphasia (in dominant hemisphere lesions) may result

Diagnostic Procedures Examination of the *cerebrospinal fluid* may be of great diagnostic value but this procedure should be carried out with care particularly in those cases in which a temporal or cerebellar abscess is suspected In such a case removal of even a moderate quantity of fluid can lead to herniation of the temporal lobe through the tentorial hiatus or of the cerebellum through the foramen magnum with fatal results Whenever there is evidence of increased intracranial pressure only a small amount of fluid should be removed and in the presence of marked papilledema the procedure is contraindicated The fluid usually shows an increased pressure and its protein content is often higher than 100 mg per 100 ml it rarely contains more than 100 white cells per cubic millimeter and the majority are mononuclear though a number of neutrophils may be present in the early stages The sugar content of the fluid is normal and no bacteria are seen in smears or isolated by culture *Electroencephalography* may be of considerable value in diagnosis and localization since an abscess in one cerebral hemisphere usually gives a focus of extremely slow and irregular delta activity of high amplitude *Radiography* of the skull may show displacement of the pineal body *Angiography* may localize it accurately but many surgeons prefer *ventriculography* *Air encephalography* by the lumbar route is dangerous when the intracranial pressure is raised After treatment of the abscess instillation of Thorotrast into the cavity may demonstrate its progressive decrease in size

Diagnosis In the chronic abscess with no clear primary focus of infection differentiation from intracranial tumor may be impossible except by cerebrospinal fluid examination or exploration In the more acute cases the condition is distinguished from meningitis by the absence of meningeal irritation and by the cerebrospinal fluid changes In patients with otitis media there may be confusion between temporal abscess and lateral sinus thrombosis or between cerebellar abscess and labyrinthitis However septic thrombosis of the lateral sinus is usually a more dramatic febrile illness than temporal abscess and rarely produces focal neurologic signs in a proportion of cases the Tobey Ayer manometric test will be positive Labyrinthitis can usually be recognized since it tends to give more vertigo and less headache than does cerebellar abscess and does not produce papilledema or changes in the cerebrospinal fluid

Prognosis Without treatment brain abscess is an almost uniformly fatal disease save for the very rare cases which become quiescent and thickly encapsulated and a few in which spontaneous drainage occurs via the middle ear or frontal sinus Death usually results from diffuse suppurative encephalitis increased intracranial pressure brain herniation or from rupture of the abscess into the ventricular system or subarachnoid space Before the days of antibiotics about 50 per cent of patients died despite surgical treatment after penicillin became freely available the mortality rate dropped to under 30 per cent

Late Prognosis Not all the 70 per cent of patients who survive after treatment of a brain abscess recover completely Some are left with signs of neurologic deficit varying from a mild field defect to hemiplegia Recurrent headaches intellectual impairment and anxiety states are common and about 50 per cent of surviving patients develop seizures as a sequel

Treatment During the stage of acute suppurative encephalitis to carry out an intracranial operation is to court disaster through wider dissemination of the inflammatory process In this stage every attempt should be made to isolate the responsible organism from either the cerebrospinal fluid or the primary septic focus Vigorous antibiotic therapy with the appropriate agent systemically and if possible intrathecally is indicated Sometimes a patient who appears to have all the typical symptoms and signs of a brain abscess recovers on medical therapy alone The great majority however require surgical intervention Occasionally in the presence of deepening coma and progressive neuro

Section 10 Fungous Diseases

Abraham I Braude

Except for their etiology fungous infections differ little from bacterial infections The close relationship between bacteria and fungi is apparent from transitional forms connecting the two classes and from the similarity of the pathologic changes and clinical manifestations induced by them

The intermediate or transitional forms are represented by the *Actinomyces* These possess the characteristic branched mycelium of fungi but divide by segmentation into gram positive bacillary or coccoid forms The acid fast property of one species *Nocardia asteroides* indicates a relationship to the tubercle bacillus Although actinomycosis and nocardiosis are placed among the fungous diseases in this book the causative agents remain in an uncertain position between fungi and bacteria

An important characteristic of pathogenic fungi is dimorphism growth in two distinct forms under different environmental conditions The fungi responsible for blastomycosis sporotrichosis and histoplasmosis assume unicellular yeast" forms in infected tissues but grow as mycelia and produce asexual spores on Sabouraud agar The reverse is true for the fungus causing moniliasis Another type of dimorphism is found in coccidioidomycosis The organism responsible for this infection is multicellular in vivo and in vitro but its form differs under the two conditions In the tissues it is a sac filled with multiple spores and the growth on agar is a segmented mycelium *Cryptococcus neoformans* is the only pathogenic fungus that fails to change form when environmental conditions vary

Mycotic diseases are not transmitted from one person to another Many fungous infections are acquired by inhalation of spores growing freely in nature These spores may be rectangular unicellular mycelial fragments known as *chlamydospores* or spherical bodies borne on thin mycelial stalks and called *conidia* Other infections such as sporotrichosis result from inoculation of spores directly into the skin

A few fungous diseases are endogenous in origin *Actinomyces bovis* is a normal anaerobic inhabitant of the mouth and *Candida albicans* is a normal resident of the bowel and mouth When the normal resistance of the host is reduced endogenous infection by either agent can develop Actinomycosis is often preceded by tooth extraction and overgrowth of normal saprophytic bacteria by *C albicans* in the course of antibiotic therapy can lead to moniliasis

The mechanisms whereby fungi produce disease are obscure *Cryptococcus neoformans* possess a polysaccharide capsule similar to that of the pneumococcus which seems to protect the yeast from phagocytosis This capsular material also produces mechanical injury in the nervous system It is possible that the thick walls of other fungi such as *Blastomyces dermatiditis* and *Coccidioides immitis* function similarly as a protection against leukocytes Some fungi are ingested by phagocytes but seem to flourish within these cells In histoplasmosis for example the parasites are found in enormous numbers within reticuloendothelial cells The endothelium of small vessels can become so packed with *Histoplasma* organisms that blood flow is compromised

Another possible factor in the pathogenesis of these infections is hypersensitivity In most fungous diseases the patient exhibits marked local or even systemic reactivity to intradermal injection of the causative organism In coccidioidomycosis this type of reaction is closely associated with the development of erythema nodosum and pleural effusions The occurrence of necrosis at the site of injection of fungous antigens suggests that hypersensitivity may be responsible for necrosis of infected tissues In other patients however widespread destruction of tissue can occur despite absence of dermal sensitivity

Despite the differences in morphology and life cycle of fungi and bacteria both elicit similar pathologic changes and clinical manifestations For this reason specific diagnosis can seldom be made with certainty without demonstration of the causative organism Fortunately most pathogenic fungi are easily seen in infected tissues or exudates In a few circumstances however it is necessary to rely upon epidemiologic and immunologic methods for diagnosis

The following chapters deal only with those infections in which fungi penetrate beneath the skin

numbness of the limbs and impairment of sphincter control appear Between this stage and that of ir reversible flaccid paralysis there may be an interval of only a few hours

Many authors distinguish the acute metastatic from the acute osteomyelitic syndrome on clinical grounds the interval between phase I and phase II is very much longer in the osteomyelitic cases lasting days or even weeks but thereafter the *disease progresses with extreme rapidity It is also* true that there occur occasional chronic cases in which the march of events and the clinical picture are both attenuated and the illness lasts weeks or months with much less pain and no general signs of infection Despite these variations there is no doubt that the condition presents as a well defined clinical syndrome the diagnosis must be made in phase II or early in phase III if the patient is to recover

Diagnostic Procedures While radiography of the spine may be of great value in diagnosis particularly of the osteomyelitic cases there will be many instances in which an epidural abscess is present before the characteristic radiologic changes of osteomyelitis have had time to develop The most important investigation is spinal puncture It must be stressed however that when this condition is suspect spinal puncture should be performed by a skilled individual who is fully acquainted with the pathology of the probable lesion Lack of adequate care may mean that the needle will carry organisms *from the extradural to the subarachnoid space* If the puncture is performed at the level of the lesion pus will be found in the epidural space if not there will be a complete manometric spinal block and the spinal fluid will be xanthochromic containing a large amount of protein and only a few white cells With a characteristic clinical picture either of these findings is a sufficient indication for surgical exploration

Diagnosis In phase I cases of this type are often dismissed as examples of arthritis lumbago or spinal strain In phases II and III however the characteristic combination of fever root pain and exquisite spinal tenderness *is sufficient to exclude* such conditions as prolapsed intervertebral disk meningitis poliomyelitis transverse myelitis and polyneuritis *In* the uncommon chronic cases differentiation from intrathecal neoplasm on clinical grounds may be difficult but the changes found on spinal puncture will indicate the need for surgical exploration

Treatment Once the diagnosis is established the great majority of cases require immediate laminec*tomy for drainage of the epidural space* and vigorous antibiotic therapy should be continued Very occasionally if the abscess is situated below the termination of the spinal cord there may be recovery with antibiotics alone Scrupulous observation is necessary and neurologic signs are an indication for immediate surgery

ough search is made by diluting the pus with saline and filtering through gauze They are white yellow or brown and stand out sharply against the background of blood tinged pus The conclusive finding of course is the demonstration of gram positive filaments or bacilli which fail to grow aerobically on conventional laboratory media Granules of other organisms (staphylococci *Nocardia* *Monosporium*) fragments of caseous material and clumps of pus cells or fibrin may be confused with actinomycotic granules The technique for recovery of *A bovis* from the infected material differs from that of most other pathogenic fungi in two important respects (1) Animal inoculation is of no value and (2) Sabouraud medium will not support its growth Cultural isolation of *A bovis* is not difficult if any of several anaerobic methods is used Inoculation of Brewer s thioglycollate medium or glucose agar shake cultures is simple and satisfactory

Biopsy examination may establish the diagnosis if the actinomycotic colony ("ray fungus) is observed microscopically Demonstration of the organism can be exceedingly difficult requiring careful search of many sections

Intradermal or serologic tests with *A bovis* or its fractions are of no diagnostic aid Radiologic examination is rarely of specific value because the intrathoracic lesions resemble tuberculosis or tumor and those in bone cannot be distinguished from bacterial osteomyelitis

Treatment Penicillin and the tetracycline antibiotics are effective in treatment When either is administered in large doses over long periods of time remarkable improvement may be expected even when the purulent processes are inaccessible to surgical drainage Many recent reports indicate that the tetracycline drugs (chlortetracycline oxytetracycline tetracycline) are superior to penicillin When the tetracyclines are given in doses of 500 mg every 6 hr there is a reduction in pain and swelling within a few days as well as gain in strength increase in weight and prompt defervescence Treatment should be continued for at least a month or much longer if persistent lesions can be demonstrated by physical examination or radiologically Because penicillin is no more effective than the tetracyclines and because it requires repeated intramuscular or intravenous injection of large doses for long periods of time it should be reserved for those patients who cannot tolerate the tetracycline drugs The optimum dose of penicillin is not known At least 1 million units daily should be given intramuscularly for 4 to 6 weeks and longer if healing is still incomplete

Surgical drainage or excision of accessible actinomycotic lesions is a valuable adjunct to chemotherapy although surgery alone is of little value Older treatments such as iodides irradiation or the sulfonamides have no place in the current therapeutic regimen for actinomycosis

148 CRYPTOCOCCOSIS

Abraham I Braude

Definition Cryptococcosis is a highly fatal infection caused by *Cryptococcus neoformans* an encapsulated yeast with a special predilection for the central nervous system Cryptococcosis can also involve the lungs bones and skin and occurs with increased frequency in patients with leukemias or lymphomas

Etiology Members of the genus *Cryptococcus* to which *C neoformans* belongs form neither mycelia nor spores and reproduce entirely by budding The cells of *C neoformans* are spherical measure 5 to 15 μ in diameter retain the Gram stain and are surrounded by a capsule which may become so large that its total diameter is three times that of the cell proper The capsular material contains a polysaccharide which is responsible for the slimy appearance of the yeast in culture and for the myxomatous character of cryptococcal lesions

The organisms grow readily on various media at room temperature and at 37 C On Sabouraud glucose agar visible growth appears within a few days at 37 C and gradually assumes a characteristic

and mucous membranes to involve the underlying tissues and viscera

147 ACTINOMYCOSIS

Abraham I Braude

Definition Actinomycosis is a noncontagious suppurative infection produced by an anaerobic organism normally resident in the mouth The disease is characterized by chronic inflammatory induration and sinus formation

Etiology The causative agent is a branching gram positive filamentous organism Attempts have been made to recognize two separate anaerobic species of the genus *Actinomyces* on the basis of their pathogenicity for man or cattle Those who would make this differentiation have designated *Actinomyces bovis* the culturally smooth form as the agent responsible for actinomycosis in cattle and *A israeli* the rough form as the etiologic agent of human actinomycosis Because these smooth and rough forms are probably variants of the same species the term *Actinomyces bovis* will be used here for all pathogenic anaerobic actinomyces

Actinomyces bovis differs from all other actinomyces in its intolerance of free oxygen and its failure to grow on Sabouraud s medium It also has a much greater tendency to fragment into short gram positive rods (arthrospores) On blood agar colonies require 4 to 6 days of anaerobic incubation at 37 C to reach a size of 1 to 2 mm Although most strains require anaerobic conditions for isolation some can be subcultured aerobically in 10 to 20 per cent carbon dioxide *A bovis* has never been found outside the human or animal body and case to case transmission has never been known to occur

Pathogenesis The saprophytic actinomyces produce disease only under circumstances which favor the growth in the tissues The oxidation reduction potential of normal tissues is probably too high for the multiplication of *A bovis* but in devitalized tissues it reproduces and gains a foothold from which it can spread The frequency of actinomycotic lesions of the face and neck may be explained not only by the greater population of *A bovis* in the pharynx but also by the frequent trauma to which these tissues are subjected by eating by dental procedures or by infection with oral bacteria Appropriate anaerobic conditions are also present in atelectatic areas of the lung after aspiration and *A bovis* sometimes predominates among the aspirated organisms and produces pulmonary actinomycosis It is also possible that pulmonary actinomycosis may be hematogenous in origin an infected area in the mouth serving as the primary site The exact mode of development of abdominal actinomycosis is unknown but the frequency with which the cecal region is involved suggests that the conditions here favor devitalizing injury Occasionally perforation by a foreign body precedes infection

From foci in the jaw lung or bowel actinomycosis may spread by contiguity or through the blood to the liver spine brain kidneys internal genitalia spleen and subcutaneous tissues

The inflammatory reaction to *A bovis* is characterized by three features (1) granulomas (tubercles) containing multinucleated giant cells (2) extensive necrosis and (3) intense fibrosis The so called "sulfur granules which occupy a prominent place in the inflammatory lesion of actinomycosis are composed of intertwined mycelial filaments

Clinical Manifestations The essential feature of actinomycosis is a painful indurated swelling This lesion may appear over the jaw a week or more after such trauma as tooth extraction or compound fracture of the mandible As it increases in size points of suppuration the openings of fistulas appear on the bluish red surface of the edematous skin

The lower lobes of the lung are frequently affected and the disease can suddenly become evident only when the pleura and chest wall are involved by direct extension from the lung Until then the patient may notice only fever, cough and expectoration Physical examination at this time reveals a diffuse tender indurated thoracic swelling with evidence of pulmonary consolidation Actinomycosis of the lower chest can extend through the diaphragm to produce subphrenic or hepatic abscess

Abdominal actinomycosis is often mistaken for appendicitis carcinoma of the cecum tuberculosis or amebiasis Patients with abdominal actinomycosis have been subjected to surgery for drainage of a supposed appendiceal abscess the true nature of the disease being recognized only when an indurated draining sinus remains and stubbornly refuses to heal Actinomycosis may also be mistaken for tumor of the reproductive organs in women or for tuberculous psoas abscess Peritonitis is rare

In the rare case of disseminated actinomycosis lesions appear in all parts of the body as a result of hematogenous spread A prominent feature is the presence of painful indurated nodules under the skin of the legs arms back and scalp

Diagnosis The disease is easily recognized by detecting *A bovis* in pus obtained from sinuses empyema fluid or abscess cavities Interpretation of the finding of *Actinomyces* in sputum is difficult of course because the organisms are normal inhabitants of the mouth Sulfur granules vary in size from several microns to 3 mm in diameter Large granules are nearly always found if a thor

peculiar to *C neoformans* Biopsied material should also be inoculated intraperitoneally in white mice *Cryptococcus neoformans* is highly pathogenic for these animals and readily demonstrated microscopically in sections or smears of their brains Serologic or skin tests are of no value in diagnosis

Treatment There is no dependable treatment Occasionally improvement has been reported after use of sulfadiazine Actidione cryptococcal vaccines and 2 hydroxystilbamidine but their value is hard to judge because of the tendency for cryptococcosis to undergo spontaneous remissions Surgical excision has often proved to be effective for cryptococcal masses in the skin bone lung or central nervous system

Because of the susceptibility of cryptococci to heat hyperthermia has been suggested as a form of treatment but has received little trial

149 NORTH AMERICAN BLASTOMYCOSIS

Abraham I Braude

Definition North American blastomycosis is a fungous infection of the skin and viscera caused by *Blastomyces dermatiditis* It is one of the few systemic mycoses amenable to specific chemotherapy

Etiology In infected tissues *B dermatiditis* has the appearance of a yeast forming single buds from 3 to 24 μ in diameter Two features aid in recognition (1) its thick wall spoken of as "double contoured" because the inner and outer margins can be seen and (2) the wide opening between parent cell and bud at the base of attachment

In culture the fungus is dimorphic and appears as the wrinkled waxy yeast form on blood agar incubated at 37 C or as a mold with branching hyphae on Sabouraud agar at room temperature On microscopic examination the cultured yeast may be identical with that in the infected lesions or may have abortive mycelia The mycelia give rise to oval or pear shaped exogenous spores known as *conidia*

Although mice inoculated with *B dermatiditis* sometimes develop infections its virulence for laboratory animals is generally low

Pathogenesis and Pathology The skin has been proposed as a portal of entry of the fungus because of the prominence of cutaneous lesions and because infections have followed injury to the skin The lung is also a likely portal through which the fungus could gain entry in dust but it has never been cultured from the soil During the epidemic in Grifton N C in 1954 (Smith Harris Conant and Smith) all patients had pulmonary disease and only one had a blastomycotic lesion of the skin yet a respiratory mode of transmission could not be established

The characteristic pathologic features are found in the lung and skin Pulmonary lesions consist of focal granulomas or diffuse purulent pneumonia and vary in size from miliary nodules to confluent areas involving an entire lobe The granulomas can undergo caseation and fibrosis *Blastomyces dermatiditis* is often found within giant cells or other phagocytes facilitating differentiation from tuberculosis

The characteristic cutaneous lesion consists of microabscesses just beneath the epidermis surrounded by a granulomatous reaction The epidermis itself often becomes so hyperplastic that it resembles an epithelioma

Dissemination of the infection to the brain bones urogenital tract liver spleen and lymph nodes can occur

Clinical Manifestations In the typical case of systemic blastomycosis the onset is insidious The patient may seek medical attention because of a persistent "chest cold" low grade fever weight loss or progressive disability Physical examination and roentgenogram of the chest disclose evidence of pneumonia which can involve any segment or lobe of the lung Cavitation is frequent and mediastinal lymph nodes may be prominently enlarged Hemoptysis purulent sputum chest pain and dyspnea appear as the disease progresses Although the pulmonary infection can subside spontaneously extrapulmonary lesions of the skin *bones joints* and viscera eventually call attention to dissemination of the infection in many patients These metastatic suppurative lesions are accompanied by an increase in fever sweats chills and weakness Death in the untreated infection sometimes occurs less than 6 months after the onset but most patients live for a year or two The over all mortality rate in the systemic form of blastomycosis is said to be 92 per cent in patients who have been fol

brownish slimy appearance Unlike other pathogenic yeastlike fungi cryptococci never form mycelia regardless of temperature of incubation or culture medium Most cells of *C neoformans* are killed in 24 hr at temperatures of 40 6 C or higher

Pathogenesis and Pathology Cryptococci resembling *C neoformans* have been isolated from soil bird droppings the surface of fruit and from the skin and intestinal tract of normal man Hence *it is possible for infections to be either of endogenous or exogenous origin* Whatever the mode of entry may be the organism ultimately finds its way to the nervous system in most cases of cryptococcosis Although the neurologic disturbances overshadow those produced elsewhere there is good evidence that foci of infection are usually established in the lung and other viscera before dissemination to the brain and the meninges occurs Often the pulmonary foci give rise to no clinical findings although they can be detected if a careful search is made at postmortem examination

Penetration of tissues by the cryptococcus does not evoke the active inflammatory response observed with other fungi or bacteria The cellular reaction is very slow to develop and is seldom intense *The cryptococcus seems to meet little* resistance in the body and frequently proliferates so freely that macroscopic masses of gelatinous yeasts fill the lesions Older lesions occasionally show granulomatous reactions The small number of cryptococci observed within such exudates suggests that they are capable of destroying the organism This may account in part for the clinical fact that lymphomatous diseases involving the mononuclear cells lower resistance to cryptococcal infection At other times however many cryptococci are present within mononuclear and giant cells It is unusual to see necrosis of the host tissue in cryptococcosis

Granulomas or gelatinous cryptococcal masses can appear in the nervous system lungs bones or skin *In the nervous system lesions usually develop* in the meninges at the base of the brain with resulting involvement of the brain stem cranial nerves and cerebellum Large masses of yeast may accumulate in the subarachnoid space and extend diffusely along the perivascular spaces into the brain substance to produce cystic nodules Because the fungal masses shrink after fixation of the brain in formalin cystlike spaces remain These spaces were thought to result from a histolytic action of the fungus by early observers who named the yeast *Torula histolytica* In the lung the disease may be scattered diffusely in the form of miliary nodules or solitary granulomas easily mistaken for pulmonary neoplasms may occur Pulmonary cavitation or hilar lymphadenopathy is extremely rare These characteristics of the cryptococcal pulmonary lesion are helpful in distinguishing the disease from tuberculosis sarcoidosis and other mycoses

Clinical Manifestations Most patients with cryptococcal infection come under the care of a physician after the onset of neurologic manifestations Complaints of severe headache diplopia dizziness ataxia vomiting tinnitus memory disturbances or Jacksonian convulsions are common Fever is usually low and can be absent Many patients die within a few months but some have lived for many years as the disease undergoes remissions and relapses

When pulmonary infection is present in the absence of meningoencephalitis the patient is generally *free of constitutional symptoms The disease* is detected when roentgenographic examination of the chest shows a dense *solitary* infiltration of the lower portions of the lung

Involvement of bones in the absence of disseminated disease is rare and cryptococcosis of joints is almost always secondary to adjacent osseous lesions

Disseminated infection can also lead to skin lesions which take the form of multiple nodules of papules which vary from a few millimeters in diameter to masses resembling strawberries in size and color

In every patient with cryptococcosis the possibility of an underlying disorder such as Hodgkin s disease lymphosarcoma or leukemia should be considered

Diagnosis Cryptococcal meningitis must be distinguished from other diseases which present the syndrome of aseptic meningitis (p 1071) such as brain abscess tuberculous meningitis and coccidioidal meningitis In each of these the spinal fluid is sterile by ordinary cultural methods and may contain from a few to several hundred mononuclear cells an increased amount of protein and a reduced concentration of glucose Because *C neoformans* is recovered with much greater ease *than the etiologic agents* of the other diseases culture of the spinal fluid is the decisive procedure in differential diagnosis The cryptococcus is isolated on Sabouraud s agar at room temperature and can usually be recognized after 1 to 2 weeks In tuberculous and coccidioidal meningitis positive cultures are much fewer and in uncomplicated brain abscess the spinal fluid is sterile Cryptococcal cells may also be found by direct microscopic examination of sediment from centrifuged spinal fluid Mixing a drop of sediment with India ink on a glass slide facilitates the recognition of the mucinous capsule The organism can also be seen in tissue removed by biopsy Intracellular forms with small capsules can resemble *Histoplasma capsulatum* but may be differentiated by mucicarmine which stains the capsular mucopolysaccharide

personnel The mycelium and its spores are pathogenic for various laboratory animals The mycelial form is converted to a thick walled spherule filled with endospores in animal tissues

Pathogenesis and Pathology Coccidioidomycosis is acquired by inhalation of *chlamydospores* in endemic areas in the semiarid regions of the Southwestern United States and the Chaco district of Argentina The majority of infections occur during the dry seasons particularly after exposure to dust storms The fungus is thought to grow in the soil in rainy weather and become disseminated in dust during dry weather This concept is supported by isolations of C immitis from soil and from desert rodents These animals are thought to be a reservoir for contamination of soil

The inhaled spores are carried to the terminal bronchioles and alveoli where the first reaction is an outpouring of polymorphonuclear leukocytes fluid and a few mononuclear cell In most cases the organism is probably killed or at least arrested at a stage when the lesion is too small to be detected by clinical means In others the organisms proliferate and elicit a varying inflammatory response which appears to depend on the rate of multiplication of the fungus The phase of rapid multiplication as manifested by frequent discharge of endospores from the ripened spherules elicits suppuration and an exudate rich in polymorphonuclear leukocytes The phase of slow multiplication with infrequent rupture of spherules produces a granulomatous reaction in which epithelioid cells and giant cells predominate Although polymorphonuclear leukocytes congregate about the point of rupture of a spherule and actually invade the broken capsule attempts at phagocytosis by these cell are unsuccessful As the released endospores develop into spherules the neutrophilic reaction gives way to proliferating mononuclear cells which often are able to ingest the fungus

Either phase of this inflammatory cycle may predominate or a mixture of the two may be found Rapidly progressive infections produce large areas of confluent suppurative pneumonia and necrosis of adjacent bronchi In contrast granulomatous lesions contain exudates composed almost exclusively of mononuclear cells and giant cells which fill the alveoli but leave their walls intact Both reactions are accompanied by involvement of the overlying pleura and of the hilar and mediastinal lymph nodes Ultimately the bronchopneumonia in most patients resolves or heals by fibrosis in others the lesions are permanently arrested but persist as cavities or solid nodules

Recovery is accompanied by the development of hypersensitivity to the fungus This hypersensitivity is apparently responsible for at least two special pathologic manifestations (1) *erythema nodosum* this is a sterile focal nodular granulomatous reaction usually limited to the skin of the lower extremities and characterized by extravasation of red cells into the lesion (p 1710) (2) *pleural effusion* It is believed that rupture of a pleural granuloma discharges antigenic material onto the sensitized pleural membranes

In patients who do not develop dermal hypersensitivity the infection spreads systemically to involve lymph nodes spleen bones liver kidney meninges skin adrenals and pericardium In the meninges the two inflammatory reactions can take special forms (1) the granulomatous reaction is commoner and produces a firm plastic lesion which encloses the brain stem and other structures in a rigid mass of tissue (2) the suppurative reaction results in outpouring of polymorphonuclear leukocytes with little granulomatous change In either type but especially in the granulomatous the involvement of the brain stem can lead to severe hydrocephalus

Clinical Manifestations The infection may be either benign or disseminated The benign infection so-called "desert fever" is self limited As many as 50 per cent of benign infections are asymptomatic The remainder are accompanied by symptoms like those of influenza or pneumonia After an incubation period of 1 to 3 weeks the patient experiences fever chills fatigue headache and symptoms of respiratory infection The most frequent complaint is poorly localized chest pain aggravated by breathing or coughing Some patients also experience substernal pain on swallowing of sufficient severity to prevent eating solid food A nonproductive cough is common but hemoptysis is infrequent Physical findings are scant except in those patients (3 to 20 per cent) who develop erythema nodosum or pleural effusion Although hydrothorax may be massive and require repeated thoracenteses it eventually resorbs without further difficulty

Despite the paucity of signs in the chest prominent abnormalities are found in roentgenograms These include focal areas of pneumonic infiltration hilar and mediastinal lymphadenopathy pulmonary nodules or cavities and pleural effusion The commonest are single or multiple infiltrations which may appear in any segment and can simulate secondary tuberculosis if the upper lobe is involved They usually resolve after several weeks

In about 2 per cent of benign infections a solid or cavitary pulmonary lesion remains after the active stage is over The typical cavity of coccidioidomycosis is peripheral has a thin wall and gives a cystlike appearance in roentgenograms Bronchoscopic examination may disclose stenosis and ulceration of the bronchus leading to the corresponding lobe This deep bronchial disease is responsible for

lowed for 2 years or longer without specific therapy

Primary infection of the skin (Gilchrist's disease) first appears on an unclothed area such as the hands face or forearm but not the scalp palms or soles The infection begins as a firm nodule surrounded soon by similar lesions which tend to coalesce Suppuration in the center of the nodule is followed by partial healing and fibrosis as extension occurs peripherally The hyperplasia of the epithelium gives these lesions a hard raised wartlike margin When fully developed blastomycosis of the skin presents the appearance of one or more ragged ulcers with partially healed centers and thick raised margins *The primary cutaneous infection may be* confined to the skin for months or years before it spreads to the viscera

Diagnosis Pulmonary blastomycosis closely resembles tuberculosis carcinoma of the lung aspiration pneumonitis and other fungous infections including coccidioidomycosis actinomycosis nocardiosis and histoplasmosis Differentiation must be based on the recovery of the etiologic agent because neither clinical nor epidemiologic features are specific Most cases of North American blastomycosis are found in the Southeastern United States and in the Mississippi River Valley but the disease occurs throughout the United States and Canada Occupational history sex race and age are of no diagnostic aid

It is usually possible to find *B dermatiditis* by *microscopic examination of biopsied material sputum* or pus The thick walled yeastlike form can be readily observed if a drop of purulent material is first mixed on a slide with a drop of 20 per cent potassium hydroxide and allowed to stand at room temperature for 30 min *B dermatiditis* is readily isolated by culturing pus on Sabouraud agar at room temperature and on blood agar at 37 C Inoculation of mice or other animals is usually not a successful method for recovering the fungus

The value of the skin test for blastomycosis using killed cells or blastomycin is limited because of negative reactions in patients with disseminated infection and cross reactions in persons with hypersensitivity to coccidioidin or histoplasmin The complement fixation test is positive in high titer with sera of patients who have systemic infections The results of intradermal and serologic tests may be of prognostic value Patients with marked dermal hypersensitivity and low serum titers of complement fixing antibody are said to have a better prognosis than those with negative skin tests and high complement fixation titers Neutrophilic leukocytosis and hypochromic anemia are usually present in systemic blastomycosis

Treatment The outlook in blastomycosis has been greatly improved by the use of stilbamidine or 2 hydroxystilbamidine Either drug is given daily or every other day by slow intravenous drip in increasing doses up to 250 mg A total of 5 to 8 Gm is usually required for control of the disease Two untoward reactions have been observed with stilbamidine One of these is an unavoidable anesthesia over the distribution of the trigeminal nerve it appears several months after injection of the drug and lasts for at least 2 years Unless the drug is shielded from light it deteriorates rapidly and the breakdown products can cause hepatic and renal injury 2 Hydroxystilbamidine is less likely to produce neuropathy and has the additional advantage of being stable to light A diet low in proteins and purine has been advocated during treatment because these substances antagonize the action of the stilbamidines Although these agents disappear immediately from the circulation after intravenous *injection they accumulate in the tissues and persist* there for as long as a year Surgical excision of pulmonary cavities or destroyed tissues is sometimes required in addition to chemotherapy

Iodides and vaccines no longer hold an important place in the treatment of blastomycosis

150 COCCIDIOIDOMYCOSIS

Abraham I Braude

Definition Coccidioidomycosis is an infection acquired by inhalation of *Coccidioides immitis* a fungus existing only in the mycelial phase in nature and converted to a spherule in tissues Although most infections are mild or unapparent *C immitis* may produce a fatal disseminated disease with destructive lesions in the lungs lymph nodes spleen liver bones kidneys and brain

Etiology Unlike other dimorphic pathogenic fungi *C immitis* can be cultured only in the mycelial phase It grows *readily at room temperature* or at 35 C and produces white cottony mycelia As a culture ages the segmented mycelium breaks up into thick coated rectangular *arthrospores* 2 by 4 μ in size These arthrospores can survive in stored cultures and are highly infectious for laboratory

151 HISTOPLASMOSIS

Abraham I Braude

Definition Histoplasmosis is a protean infection caused by the dimorphic fungus *Histoplasma capsulatum* an organism characteristically found as a tiny body within reticuloendothelial cells The disease varies from mild or unnoticed respiratory infection to widely disseminated lethal disease characterized by fever anemia hepatomegaly splenomegaly leukopenia pulmonary lesions ulcerations of the gastrointestinal tract and adrenal necrosis

Etiology Although *H capsulatum* grows on Sabouraud agar at room temperature as a spore bearing mold it is transformed immediately upon animal inoculation into nonencapsulated oval yeast like cells measuring 2 by 4 μ In histologic section the protoplasm is shrunken so that the unstained space beneath the cell wall has the appearance of a capsule The name *capsulatum* is based on a misinterpretation of the nature of this unstained space The fungus also grows in the yeastlike phase if incubated at 37 C in sealed tubes of blood agar The most distinctive cultural feature however is the tuberculate *chlamydospore* found only on mycelia it is round 10 by 20 μ in diameter and covered with warty projections Another smaller spore not distinguishable from that of *Blastomyces dermatiditis* is also present on the mycelium

Pathology and Pathogenesis The source of human infection is probably soil containing spores of *Histoplasma* Several studies have emphasized the isolation of the fungus from soil in areas inhabited by chickens but conclusive evidence connecting human infection with a definite animal reservoir is still lacking In most cases the portal of entry is probably the lung but the gastrointestinal tract must also be considered in patients whose initial lesions are in the mouth and pharynx

The basic pathologic process is the multiplication of *H capsulatum* in cells of the reticuloendothelial system The yeast form multiplies extensively and greatly distends the cells Proliferating histiocytes encroach on parenchymal cells and this leads to enlargement of the infected organ The liver lymph nodes lung spleen adrenal bowel and marrow may be affected by this diffuse reticuloendothelial disturbance in disseminated histoplasmosis

In addition to the diffuse lesions of the reticuloendothelial system the tissues contain lesions consisting of nodular accumulations of epithelioid cells and giant cells of the Langhans type The non *caseous granuloma probably represents an effective* defensive action and histoplasma organisms are difficult to demonstrate in the epithelioid cells of such a lesion

Caseous necrosis may accompany both types of lesion The adrenals which are involved in nearly all disseminated infections are often massively enlarged Caseous necrosis is usually present in the center of the pulmonary granulomas which resemble those of cavitary pulmonary tuberculosis Necrotizing histoplasmosis may also take the form of renal papillitis Extracellular forms of histoplasma are readily found in the necrotic areas of all organs by special stains (periodic acid–Schiff Gridley) These extracellular organisms may be much larger than the intracellular ones appear distorted and occasionally assume the mycelial form

Clinical Manifestations The signs and symptoms of histoplasmosis range from those of a slight self limited infection to the overwhelming disturbances of fatal disseminated disease The high incidence of positive intradermal reactions to histoplasmosis in healthy persons in many parts of the world indicates that most infections by *H capsulatum* are unapparent or very mild This variability in severity is observed among different persons involved in the same outbreak Severe infections are characterized by prolonged fever coma dyspnea chest pain weight loss prostration widespread pulmonary infiltrates hepatomegaly and splenomegaly Other infected persons may exhibit only a benign acute pneumonitis lasting a week or less while still others are entirely free of symptoms Widespread ill-defined noncalcified pulmonary infiltrates of miliary size or larger are found in symptomatic infections and may also be present although less extensively in the asymptomatic ones Eventually pulmonary lesions either disappear or calcify In the east central part of the United States there is a high incidence of pulmonary calcification in persons who have negative tuberculin and positive histoplasmin skin tests

Least resistance to histoplasmosis seems to be encountered in young infants and in adults after the fifth decade Most cases of disseminated infection have occurred at these extremes of life but with somewhat different clinical manifestations in the two groups In the infant there are fever emaciation anemia and leukopenia and evidence

the distention of the cavities Residual solid lesions can be as large as 3 cm in diameter Both solid and cavitary lesions are commoner in the upper lobes Calcification is rare

In a relatively few individuals (0 05 to 0 2 per cent) the primary infection progresses to the disseminated form of the disease Dissemination usually occurs within a few months of infection Dark skinned persons are more vulnerable to this type of spread and experience a higher death rate Among Negroes and Filipinos 85 to 90 per cent with dissemination succumb as compared to 50 per cent of whites Patients who develop progressive coccidioidomycosis do not give a history of erythema nodosum

The course of disseminated infection is marked by the appearance of fungating or ulcerating skin lesions multiple pulmonary nodules or cavities widespread destructive lymphadenopathy osteomyelitis and meningitis Weight loss fever and weakness are the outstanding systemic manifestations and the course is often rapid with death occurring in less than a year If vital organs are spared however patients with disseminated coccidioidomycosis may feel surprisingly well continue to work and even gain weight despite the presence of large numbers of *C immitis* in the sputum or subcutaneous abscesses The meningeal form is invariably fatal but even this is compatible with survival for several years In the presence of meningitis with progressive hydrocephalus patients experience severe headaches cranial nerve palsies memory disturbances and disorientation The spinal fluid shows 100 to 200 cells mostly mononuclear elevated protein and frequently a reduction in glucose concentration

Diagnosis With the exception of meningitis *C immitis* is easily recovered from the lesions of disseminated coccidioidomycosis by direct examination and cultures of exudates or biopsied tissues The characteristic spherule with endospores is best seen in purulent material treated with 20 per cent potassium hydroxide Occasionally in biopsied tissue spherules may all be immature and contain no endospores making them indistinguishable from *Blastomyces dermatiditis* Cultural identification becomes essential for diagnosis On Sabouraud agar mycelial growth appears in 4 to 8 days and inoculation of mice produces multiple necrotic lesions containing spherules In meningitis only a few spherules appear in the spinal fluid despite the presence of large numbers in the granulomatous exudate around the brain stem Occasionally the culture of 20 to 30 ml of spinal fluid yields positive results but sometimes the diagnosis can only be based on serologic tests

Serologic tests are performed with coccidioidin a filtrate from cultures of *C immitis* By the third week of primary infection precipitins are found in the serum of 91 per cent of patients with symptomatic infection but in only 7 per cent of asymptomatic individuals Complement fixing antibodies appear later and persist longer than precipitins in nondisseminated coccidioidomycosis they are almost always present in the disseminated disease Intradermal tests with coccidioidin are of value in the recognition of primary benign infections because they become positive before the precipitins appear but in disseminated infection the skin test is frequently negative

The roentgenographic appearance of pulmonary lesions is suggestive of primary coccidioidomycosis if hilar lymphadenopathy progresses while the parenchymal infiltrate is subsiding or if the adenopathy is associated with multiple areas of pneumonitis A residual smooth thin walled cavity without surrounding parenchymal infiltration is also characteristic of the primary form of the disease Other residual lesions include calcified or noncalcified nodular foci and localized bronchiectasis In disseminated pulmonary infection the commonest picture is that of multiple infiltrations accompanied by pleural involvement and prominent hilar or mediastinal lymphadenopathy

The only remarkable hematologic finding is eosinophilia which may reach 35 per cent of the total leukocyte count in the primary disease

Treatment Scattered reports suggest that Actidione prodigiosin and the stilbamidines may be of value in an occasional patient but chemotherapy is usually ineffective in disseminated coccidioidomycosis Variations in results of therapy may be related to differences in sensitivity among strains of the fungus or to differences in the degree of endosporulation Large numbers of endospores packed within spherules are presumably sheltered more from the antifungal drugs than single immature spores

Primary surgical excision of residual pulmonary foci is indicated if these lesions become troublesome because of secondary infection or hemoptysis Dissemination of the disease from these foci almost never occurs

SPOROTRICHOSIS

Definition Sporotrichosis is a chronic infection due to *Sporotrichum schenckii* It is characterized by the formation of suppurating nodules along the lymphatics of the skin and subcutaneous tissues Hematogenous dissemination is rare

Etiology The fungus *S schenckii* exhibits the dimorphism On Sabouraud agar at room temperature its growth is mycelial but in the tissue it takes the form of tiny cigar shaped yeast cells The yeast phase can be produced in vitro by incubation at 37 C on blood agar containing cystine

Pathogenesis and Pathology The fungus lives as a saprophyte on vegetation and penetrates the hands when the skin is broken Many cases have followed injury by thorns and an outbreak of sporotrichosis occurred among South African natives exposed to *S schenckii* growing on timbers supporting a gold mine

After penetrating the skin the fungus spreads up the extremities and evokes nodular lesions along the thickened lymphatics Microscopically the nodules are granulomas with central necrosis In exceedingly rare infections the organism may become disseminated throughout the subcutaneous tissues the liver testicles bone and kidney Disseminated disease is not usually accompanied by primary infections of the extremities and its portal of entry therefore is believed to be the mucosa of the gastrointestinal tract

Clinical Manifestations There is a marked disproportion between symptoms and findings A chain of hard reddened discrete lumps extends up the arm or leg to the axilla or groin and the intervening lymphatics are red and thickened but there is no pain fever or other constitutional symptoms Older nodules often rupture to produce fistulas or ulcers In the rare patient with disseminated sporotrichosis constitutional symptoms may be marked and the disease rapidly fatal Unlike other disseminated mycoses sporotrichosis almost never involves the lungs or central nervous system

Without treatment sporotrichosis does not heal and the lesions persist often with secondary bacterial infections

Diagnosis The fungus cannot be seen upon microscopic examination of biopsied material or pus in most cases Cultural isolation is invariably successful however if pus is aspirated from an unbroken nodule and inoculated onto Sabouraud agar The growth at first has the soft creamy character of bacterial colonies and later develops a wrinkled dark brown appearance without the cottonlike filament of most molds Microscopically typical clusters of pear shaped spores are found at the tips of conidiophores arising from the tangled mass of delicate branched mycelia If the mold or the pus itself is inoculated intraperitoneally into mice or rats numerous yeast forms will be seen in lesions of the peritoneal cavity or testicle in which they take the form of gram positive cigar shaped rods within polymorphonuclear leukocytes

Recovery of the organism by these techniques permits ready differentiation of sporotrichosis from other chronic infections of the subcutaneous tissues such as syphilis tularemia blastomycosis coccidioidomycosis and tuberculosis (see p 907) The hard sporotrichotic lesions are sometimes mistaken for syphilitic gummas and their response to iodides is interpreted as therapeutic proof of the diagnosis

Treatment Both forms of sporotrichosis are almost *invariably dramatically cured by saturated* potassium iodide This should be given orally in starting doses of 10 drops t i d after meals and gradually increased to the point of maximum tolerance Treatment should be continued for a month after lesions disappear Additional local therapy may be required for cutaneous ulcers which should be painted with tincture of iodine It may also be necessary to excise the epidermal lesions as these do not usually subside with oral iodides

MONILIASIS (Candidiasis)

Definition *Moniliasis is a common mild mucocutaneous* infection due to *Candida albicans* This fungus is also an unusual cause of widespread visceral infection

Etiology Among the many species of *Candida* only *C albicans* is pathogenic for man On the usual nutrient laboratory media *C albicans* grows almost exclusively as a budding yeast in creamy white colonies but produces both mycelia and yeastlike cells in infected tissues

Pathogenesis *Candida albicans* resides normally on the mucous membranes and is frequently cultured from the mouth and feces of persons in good health The rate of cultural isolation from feces in numerous surveys has ranged from 14 to 19 per cent In debilitated infants and sometimes in adults the fungus may produce white patches on the buccal mucosa and initiate mild inflammation reaction in the underlying tissues In pregnancy and diabetes *C albicans* frequently establishes a mild superficial infection of the vagina Presumably the high glycogen content of the vaginal mucosa in pregnancy and the glycosuria of diabetes favor its growth *Candida* multiplies excessively in the bowel or mouth if the normal bacterial flora are suppressed by chemotherapy Although true infection seldom accompanies this overgrowth of *Candida* the large

of widespread involvement of many viscera including the liver spleen lung bowel lymph nodes adrenals skin kidney brain eye or endocardium While the same degree of dissemination may occasionally occur in the adult usually the visceral involvement is less widespread Unlike the disease in infancy adult histoplasmosis shows a marked predilection for males Histoplasmosis of the lips mouth nose and larynx occurs almost exclusively in adults and is the initial manifestation in about one third of the fatal cases Among the various syndromes encountered are subacute vegetative endocarditis massive lymphadenopathy resembling tuberculosis or lymphoma various forms of pneumonia including an interstitial type with capillary alveolar block and meningitis The last is characterized by signs of basilar localization with spinal fluid findings and a clinical course identical with those of tuberculous meningitis

In addition to the acute benign and disseminated infections chronic localized histoplasmosis occurs in adults Although frequently accompanied by necrosis or ulceration this form is basically a granuloma and its tendency to remain localized is probably related to the effective defensive activity of the granulomatous reaction

Two main clinical types are encountered (1) *Pulmonary* This may resemble pulmonary tuberculosis in all respects The patient can be asymptomatic or complain of a chronic and occasionally productive cough Roentgenograms will show lesions identical with those of reinfection tuberculosis sometimes with cavitation and accompanied by consistently positive cultures of sputum for *H capsulatum* (2) *Mucocutaneous* Ulcers of the mouth tongue pharynx gums larynx penis or bladder are rare lesions found only in adults Regional lymphadenopathy is common in these types

Diagnosis Isolation of *H capsulatum* is not difficult in disseminated or chronic localized infections if cultures are made of bone marrow blood biopsied lesions sputum or exudate from an ulcer After incubation of infected material on Sabouraud agar at room temperature there appears a white cottony colony which later turns brown and produces the diagnostic tuberculate chlamydospores Material may also be cultured at 37 C on Francis medium or blood agar but the growth is yeastlike and the diagnostic spores are not found Isolation from sputum is best accomplished in mice because contaminants are suppressed and the mouse is extremely susceptible to infection by *Histoplasma* The animal does not die but subculture of the spleen one month later on Sabouraud agar yields the organism *Histoplasma* may also be seen in bone marrow material from open or biopsied lesions and occasionally in blood smears of terminally ill patients Special fungus stains (periodic acid-Schiff Gridley) should be used Certain intracellular forms of *Cryptococcus neoformans* may be indistinguishable from *Histoplasma* in histologic sections unless stains for the cryptococcal mucinous capsule are employed

In those cases from which *H capsulatum* cannot be isolated indirect clues to identification are (1) history of exposure to soil or dust in an endemic area (2) positive complement fixation tests (3) positive histoplasmin skin tests and (4) development of miliary calcifications in the lung Although these criteria are not dependable individually they appear to be reliable when used together The serologic and skin tests are frequently negative in culturally proven cases of histoplasmosis and their specificity is not fully established

Histoplasmosis must be differentiated from tuberculosis sarcoid leukemia infectious mononucleosis Hodgkin s disease brucellosis and kala azar Because cortisone is frequently of value in sarcoid but can cause dissemination in histoplasmosis differential diagnosis between these two diseases is critical Biopsied tissue in both diseases contains morphologically identical granulomas For this reason the diagnosis of sarcoid should be withheld until tissues have been examined with special fungus stains In kala azar the intracellular Leishman Donovan body bears a close resemblance to *H capsulatum* and cultural isolation of the fungus may be important in distinguishing between the two

Treatment The only dependable treatment is excision of localized lesions Chemotherapy of disseminated histoplasmosis has been disappointing despite the use of many different agents including sulfonamides antibiotics and iodides Occasionally questionable benefit has been observed with stilbamidine and ethyl vanillate but these drugs are usually ineffective

instances there is direct extension along lymphatic pathways Death can occur from secondary bacterial infection

Diagnosis The characteristic granules are 0 5 to 2 mm in diameter and may be white yellow black or red Nocardial granules are easily distinguished from those of *A boydii* and other higher fungi by direct microscopic examination They are masses of radiating gram positive filaments those of higher fungi contain large segmented hyphae and numerous chlamydospores Inoculation of either type of granule on Sabouraud agar is followed rapidly by characteristic growth

Roentgenograms of the foot disclose destruction of bone which is more extensive than the external appearance and pain might indicate

Treatment Wide excision of infected tissues may slow the progress of the disease and antibacterial chemotherapy is valuable in arresting secondary infection There is no known cure however and most cases eventually require amputation of the foot

CHROMOBLASTOMYCOSIS

Definition Chromoblastomycosis is an infection of the skin produced by several species of the genus *Phialophora* and characterized by slowly progressive cauliflowerlike lesions of the legs of agricultural workers in tropical or subtropical regions

Etiology The three species *P pedrosi P compactum* and *P verrucosa* cannot be distinguished upon microscopic examination of infected tissue in which all appear as small clusters of spores with thick dark brown walls On culture however the three differ in their methods of sporulation The species most commonly found *P pedrosi* exhibits three types of spore formation (1) branching chains of spores borne at the tips of long conidiophores (2) clusters of spores forming sleeves about the hyphae and (3) balls of spores arising in the cuplike ends of very short flask shaped conidiophores *Phialophora verrucosa* forms only the third type of spore and *P compactum* is recognized by chains of spores arranged in compact masses On Sabouraud agar all three grow very slowly and will produce deeply pigmented olive or black colonies

Pathogenesis and Pathology The fungi undoubtedly live in the soil or vegetation and enter the skin of agricultural workers

Three pathologic processes are found (1) microabscesses in the dermis containing numerous fungi (2) extensive fibrosis and (3) epidermal hyperplasia and hyperkeratosis The lesions progress along the lymphatics but not beyond them dissemination through the blood or deep penetration into bone does not occur

Clinical Manifestations The earliest lesion is a papule which develops into a well circumscribed bluish lesion with a warty raised margin Although it resembles the cutaneous form of North American blastomycosis at this early stage it does not spread peripherally Instead adjacent new lesions appear over a period of years and as the epithelial hyperplasia and hyperkeratosis increase the entire area assumes a cauliflowerlike appearance Eventually the whole extremity is covered Pain and constitutional symptoms are absent unless secondary bacterial infection occurs or elephantiasis develops as a result of lymphatic scarring

Diagnosis The typical dark brown septate bodies are seen in large numbers in biopsied tissue or pus and brown hyphae can be found in crusts treated with 10 per cent potassium hydroxide For specific identification however it is necessary to culture the slowly growing fungus on Sabouraud agar

Treatment Early in the disease the lesions may be destroyed by electrocoagulation or removed by surgical excision Later in the course excision of the larger nodules leaves indolent ulcers which heal very slowly

Except for treatment of secondary infection there is no specific medical therapy The disease is never fatal however and the usefulness of the limb is retained despite its unsightly appearance

SOUTH AMERICAN BLASTOMYCOSIS

Definition South American blastomycosis is a highly destructive but curable infection that results from invasion of the nasopharynx by *Blastomyces brasiliensis* It occurs only in South America From the pharynx the disease can extend locally to regional nodes or spread to the lungs and abdominal viscera

Etiology Multiple buds on the yeastlike cell of *B brasiliensis* distinguish it morphologically from its North American counterpart *B dermatitidis* The tiny multiple buds have the appearance of a crown of small beads attached to the cell wall The fungus reproduces by budding both in tissues and when cultured at 37 C At room temperature it produces mycelia which bear spores resembling those of *B dermatitidis*

Pathogenesis In most cases the portal of entry of this exogenous fungus is the nasopharynx Here it produces a destructive lesion with gross swelling and ulceration and eventual extension to the cervical lymph nodes Occasionally the primary lesion is inconspicuous and massive enlargement and suppurative necrosis of the regional lymph nodes are the predominant pathologic changes Hematogenous spread to other lymph nodes liver spleen and bone eventually leads to suppurative or granulomatous nodules in those organs In addition to the naso-

inoculum provides a threat in debilitated persons who may develop aspiration pneumonia or even *Candida* septicemia Visceral infection can take the form of vegetative endocarditis brain abscess meningitis or pyelonephritis The visceral lesions are granulomatous nodules or abscesses containing both mycelia and yeastlike cells

Clinical Manifestations No systemic disturbances accompany the local signs of mucocutaneous infection Infection of the mucous membranes known as *thrush* gives rise only to soft white patches on the tonsils cheeks gums and tongue These patches are easily removed and leave a reddened surface Although usually self limited the disease may become chronic and spread to other mucosal surfaces or intertriginous areas in the groins the antecubital fossae the interdigital folds the inframammary areas the umbilicus and the axillae Eczematoid lesions and vesicles are also found in vulvovaginal moniliasis of pregnancy or diabetes

Aspiration pneumonia is probably the chief form of visceral moniliasis It is seen in debilitated persons often in the course of intensive therapy with tetracycline or other antibiotics and may be accompanied by mixed infection with bacteria Cough chest pain and high fever are prominent Less extensive involvements of the lung are said to heal completely or progress to chronic infections but the disease is sometimes fatal

Septicemic infections are seen in the late stages of severe debilitating disease and seem to occur most commonly in children receiving intensive antibiotic therapy The chief clinical manifestation is fever Septicemic moniliasis also accompanies vegetative endocarditis a disease that has been described mainly in narcotic addicts Meningitis is *another rare form of moniliasis it produces a* clinical syndrome similar to tuberculous meningitis

Diagnosis In thrush the organisms are seen upon microscopic examination of the white patches as a tangled mass of mycelia and yeastlike cells They grow readily on Sabouraud agar In septicemias the fungus can be isolated repeatedly from the blood Pulmonary moniliasis may be difficult to recognize because *C albicans* is a normal resident of the oropharynx and may appear in the sputum in the absence of respiratory infection For this reason it is often impossible to be certain of the diagnosis of pulmonary moniliasis unless the organism is demonstrated in pulmonary lesions at autopsy or surgery

Treatment Thrush and vaginal moniliasis are best treated by nystatin administered orally in *doses of 500 000 units t i d Topical therapy with* nystatin ointments or with alcoholic solutions of gentian violet is effective in cutaneous moniliasis Nystatin may also be of some benefit in preventing candidal pneumonia or septicemia in debilitated persons whose mouth and intestines have become overgrown with *Candida* during treatment with antibiotics The value of the parenteral form of nystatin in systemic moniliasis is uncertain

MADUROMYCOSIS (Madura Foot)

Definition Maduromycosis is a chronic destructive infection of the foot characterized by the presence of *multiple fistulas which extrude mycotic* granules The term *maduromycosis* is used here synonomously with *mycetoma* and includes not only infections caused by *Nocardia* but also those caused by higher fungi with larger hyphae

Etiology The most frequent cause of maduromycosis in the United States is a higher fungus known as *Monosporium apiospermum* the "imperfect" form of the ascomycete *Allescheria boydii* The fungus grows rapidly on Sabouraud agar as a cottony mycelium containing asexual spores borne singly or in small groups at the tips or sides of conidiophores Other higher fungi which have been isolated in maduromycosis include members of such diverse genera as *Aspergillus Penicillium Madurella Cephalosporium* and *Phialophora*

Members of the genus *Nocardia* are important causes of Madura foot outside the United States *Nocardia madurae* is found in southeastern Asia and *Nocardia brasilinesis* in South America

Pathogenesis and Pathology The fungi *A boydii N madurae* and the others listed as infectious agents in mycetoma are inhabitants of the soil and enter the tissues of the bare foot It is presumed that the fungus is introduced by trauma In rare instances the hand may also be infected

The infection begins in the outer tissues and burrows *throughout the foot to destroy bone* muscle and connective tissue indiscriminately The areas of destruction show chronic suppuration with fibrosis and are connected by multiple fistulae which rupture to the outside Mycotic granules are seen in the suppurative foci The prolonged proliferation of granulation and scar tissue leads to enlargement of the affected part

Clinical Manifestations The earliest sign is usually a small swelling on the sole or dorsum of the foot This undergoes a recurring cycle of swelling suppuration and healing Later similar lesions appear on other parts of the foot and over a period of months the destruction of deeper tissues is manifested by slight or moderate pain generalized swelling and redness The course is intermittently progressive and there may be periods of remission *Ultimately however* the foot becomes a swollen deformed mass of destroyed tissue with many fistulous openings through which mycotic granules are discharged The infection does not become disseminated to other parts of the body but in rare

guinea pigs inoculated intraperitoneally and the recovery of *N asteroides* from miliary nodules in the omentum death occurs in less than a week from pathogenic strains (4) gram positive staining reaction

Pathogenesis *Nocardia asteroides* can be recovered readily from soil Nocardiosis appears therefore to be an exogenous infection usually having its portal of entry in the lungs In almost every patient with nocardiosis (other than maduromycosis) the earliest and most extensive lesions are pulmonary These lesions are accompanied by neither the intense fibrosis nor the typical granulomatous reaction found in pulmonary actinomycosis they are acute suppurative foci containing acid fast branching nocardial filaments A well defined wall is absent a fact which probably accounts for the marked tendency of nocardial abscesses to spread to the brain and to a lesser extent to the spleen skin peritoneum and kidney

Clinical Manifestations The chief symptom is cough usually productive of a thick sometimes bloody sputum Chest pain and dyspnea are common These symptoms are usually accompanied by fever sweats chills leukocytosis weakness anorexia and weight loss The illness may be prolonged and present the picture of a chronic pulmonary infection resembling tuberculosis lung abscess or unresolved suppurative pneumonia In nearly one third of the patients this syndrome is interrupted suddenly by the acute neurologic changes of metastatic brain abscess At this time the patient may experience severe headache and focal sensory or motor disturbance The protein cell and pressure of the spinal fluid are increased but the concentration of glucose is not reduced unless the meninges are also infected Metastatic infection of the skin is frequent and produces numerous scattered abscesses or single draining sinuses of the hand chest wall or buttocks

The disease usually progresses to a fatal outcome over a period varying from months to years

Diagnosis Because patients with nocardiosis are usually suspected of having tuberculosis their sputa are likely to be examined for tubercle bacilli The usual methods for concentrating tubercle bacilli often inactivate *N asteroides* however and the fungus will not be recovered after such treatment despite the readiness with which it otherwise grows on a variety of media *Nocardia asteroides* may also be overlooked in smears stained by the Ziehl Neelsen method because it is less resistant than the tubercle bacillus to the decolorizing action of acid alcohol If nocardiosis is suspected on clinical grounds precautions must be taken therefore against killing the organism by sputum concentration methods and against overdecolorizing it The first can be avoided by concentrating with trisodium phosphate the second by using a weak solution of acid alcohol

Although sulfur granules are not found in pulmonary or disseminated nocardiosis the gram positive filamentous organisms in nocardial exudates often resemble those found in infections due to *A bovis* The two pathogens can be distinguished however by the ease with which *N asteroides* is cultivated on Sabouraud or blood agar aerobically by its acid fast staining characteristics and by its pathogenicity for guinea pigs If biopsy material is available the nongranulomatous and minimally fibrotic character of the nocardial suppurative reaction also helps to distinguish it from that seen in infections due to *A bovis* The absence of tubercles of course is valuable in differential diagnosis from tuberculosis

The isolation of a few colonies of *Nocardia* from sputum or gastric juice however is by no means diagnostic of nocardial infection This organism is widely distributed as a saprophyte and only rarely achieves pathologic significance

Treatment The sulfonamide drugs especially sulfadiazine have been used successfully in the treatment of nocardiosis Penicillin and the tetracycline derivatives appear to be ineffective although the number of cases treated have been too few for definite evaluation of these agents The apparent resistance of a patient with nocardiosis to the tetracyclines and penicillin may be used in distinguishing it from actinomycosis due to *A bovis* as well as other forms of pulmonary infection which respond to these antibiotics Patients with nocardiosis should receive 8 to 12 Gm sulfadiazine daily Despite the poor clinical results with penicillin and oxytetracycline in vitro tests are warranted to determine the sensitivity of each new strain of *N asteroides* to various antibiotics An antibiotic selected on this basis can be used to supplement the sulfonamides

pharynx primary lesions can occur in the lymphoid tissue of the cecal and appendiceal regions

Clinical Manifestations The first symptoms usually result from painful ulcers of the mouth or nose although loss of appetite abdominal pain vomiting and diarrhea may be the first complaints when ulceration begins in the gut In other cases massive lymphadenopathy precedes other manifestations In the usual infection however there is a progressive extension of lesions from the mouth and neighboring skin The lymph nodes undergo suppurative necrosis and sinuses rupture through the overlying skin The patient suffers from severe pain fever inability to eat and cachexia Depending on the rapidity of spread to the viscera bones and central nervous system the disease is fatal after periods ranging from a few months to 3 or more years if untreated

Diagnosis Microscopic examination of pus or tissue treated with 10 per cent potassium hydroxide will reveal the characteristic multiple budding cells of *B brasiliensis* in addition to cells with single buds The multiple budding cells are also found in cultures on blood agar incubated at 37 C but growth is very slow and more than a month may elapse before colonies appear

Treatment The infection responds dramatically to sulfonamide drugs Sulfadiazine or sulfamerazine in doses of 4 to 6 Gm daily has been used successfully in arresting or curing the disease

MUCORMYCOSIS

Definition Mucormycosis is a fatal infection of the cerebral blood vessels of diabetics due to an unidentified fungus assumed to be a member of the order Mucorales on the basis of its morphology in fixed tissues The disease is characterized by ophthalmoplegia and meningoencephalitis

Etiology The etiologic agent has never been cultured from the brain so that presumptive identification of the fungus has necessarily been based on the appearance of its mycelium in fixed tissue preparations Its mycelium is described as broad branching and aseptate with a diameter of 6 to 15 μ A fungus identified as *Rhizopus oryzae* a species of the order Mucorales was recovered from the ethmoid sinus of a fatal case The hyphae of this fungus in culture were identical in appearance with that in the brain Members of the order Mucorales are common saprophytic fungi in nature and grow readily on virtually any media Hence the failure of cultural isolation from the brain must be attributed to inadequate attempts rather than technical difficulties

Pathogenesis and Pathology The mold belongs to a group of common ubiquitous fungi which only rarely display evidences of pathogenicity Although a few instances of infection in nondiabetics have been described the most consistent syndrome is that resulting in patients with poorly controlled diabetes and acidosis The portal of entry appears to be the paranasal sinuses and from here the organism is thought to extend along the invaded vessels to the cerebrum and retroorbital tissues Thrombosis of arteries and veins leads to multiple infarcts throughout the brain inflammatory response to the hyphae is minimal

Clinical Manifestations Cerebral mucormycosis is characterized by three features (1) uncontrolled diabetes with acidosis (2) ophthalmoplegia and (3) signs of acute diffuse cerebrovascular disease When the patient is first seen drowsiness and semistupor are usually attributed to the metabolic disturbance but the cerebral manifestations persist and progress after the acidosis is corrected Headache and fever are prominent

In addition to complete internal and external ophthalmoplegia there may be edema of the eyelids and retina and signs of retinal vascular occlusion Nuchal rigidity and mild mononuclear pleocytosis in the spinal fluid have also been described

Diagnosis The syndrome is so characteristic that it can be recognized by its clinical features alone Antemortem confirmation of the diagnosis by isolation of the fungus has never been accomplished although cultures of spinal fluid have been attempted

Treatment There is no specific chemotherapy Treatment should be directed toward rapid correction of the hyperglycemia and acidosis with the hope that remission will occur in patients who have not suffered irreparable neurologic damage

NOCARDIOSIS

Definition Nocardiosis is an infection caused by an aerobic actinomycete The disease may appear in the form of a lung abscess and spread to the brain and elsewhere in the body or it may produce a chronic deforming granulomatous infection limited to the foot (Maduromycosis)

Etiology Pulmonary and disseminated nocardiosis usually result from infection with *Nocardia asteroides* This organism is characteristically acid fast and its bacillary form resembles the tubercle bacillus The following properties of *N asteroides* permit easy differentiation from the tubercle bacillus (1) rapid growth on Sabouraud medium or on 10 per cent blood agar with colonies appearing in 6 to 14 days at room temperature (2) the presence in exudates of long branched mycelia forms in addition to the bacillary forms (3) rapid killing of

ordinary antiseptics drying and heat It may resist cold temperatures however and can be frozen and stored for long periods without its virulence being affected The organism does not remain viable however in whole blood or plasma which has been stored at refrigerator temperature for more than 96 hr

Pathogenic forms of *T pallidum* have not been cultivated and passed serially on artificial media Strains of the organism which have been cultured are not virulent in animals and differ morphologically from pathogenic *T pallidum* Rabbits and monkeys can be experimentally infected with syphilis

Frequency Exact information is not available as to the total number of persons infected with syphilis in the United States (i e *prevalence*) or the number of new infections occurring each year (i e *incidence*) There seems little doubt however that both have decreased considerably during the period since 1947 In 1947 approximately 108 000 cases of primary and secondary syphilis were reported to the Public Health Service whereas in 1955 only 6 500 cases were reported This dramatic decline in the incidence of syphilis is largely the result of the development of rapid treatment methods mass blood testing and large scale epidemiologic measures carried out by state and Federal health departments Another factor which may be responsible for the decline in the incidence of syphilis is the widespread use of penicillin for other diseases As a result of the decrease in syphilis case rates many of the states abandoned their public health control measures There is no doubt however about the need for continuing intensive control programs

Pathogenesis Syphilis is usually transmitted by direct and intimate contact with moist infectious lesions of the skin and mucous membranes Sexual contact is by far the commonest means of infection but transfer of the disease by kissing or biting occasionally occurs Indirect transmission—i e by contaminated objects—is exceptional since the organisms quickly die if allowed to dry The disease can be spread by inoculation with infected blood as in transfusion syphilis Infection is transmitted to the fetus through the placenta *Treponema pallidum* is apparently capable of penetrating the intact mucous membrane but a small abrasion is probably required for inoculation to occur through the skin Once the spirochete has penetrated the epithelium it enters the lymphatics and can be demonstrated in the regional lymph nodes a few hours after experimental inoculation From the lymph nodes the organism spreads rapidly throughout the body by way of the blood stream This spirochetemia may occur several weeks before appearance of the primary lesion at the site of inoculation The early seeding of *T pallidum* in various tissues is the basis for many of the later manifestations of the disease

About 3 to 6 weeks after the organism has entered the body a primary lesion the *chancre* develops at the site of inoculation The chancre is usually a single ulceration of the skin or mucous membrane it heals spontaneously About 6 weeks after its appearance a generalized skin eruption known as *secondary syphilis* develops In this stage systemic manifestations are common The signs of secondary syphilis also disappear spontaneously

This sequence of events in early syphilis is variable Infection without noticeable lesions probably occurs in a high percentage of cases and many individuals with late syphilis are unable to recall either primary or secondary manifestations

Following healing of the primary and secondary manifestations the patient may show no outward signs of the infection (*latent syphilis*) Nevertheless chronic progressive inflammatory changes may be taking place in the visceral organs or in the cardiovascular or central nervous system Clinical evidence of cardiovascular syphilis or neurosyphilis may not develop for 10 to 20 years or more after the onset of the disease Occasionally the tissues of the host seem to become sensitized to the spirochetes and large destructive lesions called *gummas* result These lesions which contain very few spirochetes can occur in almost every organ of the body but are most frequent in the skin or bones

Many patients with latent syphilis do not develop late manifestations and show no evidence of syphilis at autopsy A study of patients with untreated early syphilis followed for a number of years showed that approximately one third of them achieved spontaneous cures with the development of negative serologic tests An equal number died of causes other than syphilis or developed latent syphilis with no clinical evidence of the disease other than a positive serologic test The remaining third developed serious lesions of the cardiovascular or central nervous system or benign gummatous lesions of the skin or bones

Histopathology The early lesions of syphilis are characterized by infiltration of the blood vessel walls and perivascular spaces with plasma cells large mononuclear cells and lymphocytes Spirochetes can be demonstrated by silver impregnation stains In the late lesions of syphilis there may be necrosis with granuloma or gumma formation The necrosis is thought to be the result of an exaggerated or hypersensitive response to a small number of organisms Spirochetes are rarely found These lesions heal slowly and often produce large scars

Immunity and Resistance The development of immunity in a syphilitic patient can be considered from two standpoints the resistance the patient

Section 11 Spirochetal Infections

153 SYPHILIS

Albert Heyman

Definition Syphilis is a chronic systemic infectious disease caused by the *Treponema pallidum* and usually transmitted by sexual contact It is capable of producing tissue destruction and chronic inflammation in almost any organ in the body and *can express itself in a great diversity of clinical* manifestations

History Considerable knowledge of the pathology and clinical aspects of syphilis was accumulated in the sixteenth to nineteenth centuries but it was not until early in the present century that most of the fundamental information about the disease was uncovered The etiologic agent the *T pallidum* was discovered by Schaudinn and Hoffmann in 1905 Soon afterward Wassermann and his associates introduced serologic methods of diagnosis In 1949 Nelson and Mayer introduced the *T pallidum* immobilization test following which other tests for demonstrating humoral antibodies were subsequently developed

In 1910 Ehrlich announced the discovery of arsphenamine and in 1917 Wagner von Jauregg demonstrated the value of malarial fever therapy for paresis These were the two most important advances in the treatment of syphilis until 1943 when penicillin was found by Mahoney and his associates to be effective in the early stages of the disease This drug has largely replaced the other forms of chemotherapy in syphilis

Etiology The *T pallidum* is a slender spirochete *with regular evenly spaced spirals* It varies in length from 5 to 20 μ When viewed under the dark field microscope *T pallidum* shows characteristic motility rotating on its long axis and moving slowly backward and forward The spirals usually keep their uniform shape and size although the body of the organism may bend at the middle It does not have the quick whipping movements of other spirochetes which are often found in ulcerative lesions The organism does not stain well with ordinary dyes but can be demonstrated by silver impregnation methods in fixed tissues For clinical purposes it can be demonstrated by dark field microscopy of material from primary or secondary syphilitic lesions

Treponema pallidum is readily killed by soap

administered during this period of time If the dark field examinations and serologic tests for syphilis are negative the serologic test should be repeated several times during the first 2 or 3 weeks and every few weeks thereafter for 3 months after the appearance of the lesion If the patient develops a positive serologic reaction in a high or rising titer (with or without evidence of secondary manifestations) then antisyphilitic therapy should be begun A *single serologic test* of low titer is not sufficient evidence for beginning antisyphilitic treatment if dark field examinations are negative Such tests should be confirmed several times for at least 2 or 3 weeks before treatment for syphilis is justified

Penicillin or other spirocheticidal drugs should not be given as a therapeutic test to patients suspected of having primary syphilis Healing of the genital lesion following such tests does not necessarily indicate the presence of syphilis since nonsyphilitic lesions sometimes heal spontaneously Biopsy of the genital lesions is often of value in the diagnosis of these patients

Secondary Stage The secondary stage of syphilis usually develops about 6 weeks after appearance of the chancre and is manifested by a generalized skin eruption and systemic symptoms Some patients exhibit secondary lesions without ever being aware of a primary others never develop secondary manifestations and enter the latent stage directly following the healing of the chancre

The appearance of the *cutaneous lesions* of secondary syphilis varies considerably and may be confused with many other skin eruptions The lesions most often found are papules maculopapules or follicular papules Occasionally annular pustular or rupial lesions occur Indeed almost any type of skin eruption may appear except a vesicular one The rash is usually widespread and frequently involves the palms soles and face in addition to the trunk and extremities The lesions are sometimes pruritic

The *mucous membranes* of the mouth and genitalia are often involved in secondary syphilis Syphilitic lesions of the mouth appear as painless superficial erosions on the buccal surfaces on the tongue or inside the lip When these lesions are covered with a thin grayish exudate they are known as *mucous patches* They contain a large number of spirochetes but may be very inconspicuous and the patient may not be aware of them Lesions of the palate and tonsillar area can cause a persistent *sore throat* So called *split papules* are occasionally seen in secondary syphilis and may be mistaken for herpes benign fissures or the lesions of riboflavin deficiency

Syphilitic mucosal lesions of the genitalia or perianal regions often become hypertrophic and are called *condylomata lata* These lesions are broad flat wartlike excrescences which are found on the labia majora perineum and anal region They are highly *infectious* and should be *differentiated from* condylomata acuminata which are nonvenereal pedunculated lesions

Although the clinical findings of secondary syphilis are often confined to the skin and mucous membranes many patients will present evidence of *constitutional symptoms* and widespread spirochetal dissemination Malaise lassitude headaches fever and myalgia are often noted There may be a *generalized lymphadenopathy* Localized areas of *alopecia* also occur causing a "moth-eaten" appearance of the scalp

Approximately 4 per cent of patients with secondary syphilis have involvement of the eye usually *iritis* or *neuroretinitis*

Skeletal lesions occasionally occur in secondary syphilis and are manifested by localized areas of swelling and tenderness *Arthralgia* and *hydrarthrosis* also occur but changes in the joints cannot be detected by x ray examination An acute *nephrosis* with marked proteinuria edema and hypercholesteremia is sometimes seen in secondary syphilis Evidence of *central nervous system involvement* such as paralysis of the cranial nerves or meningitis may also appear in this stage of the disease

It is apparent from the above description that secondary syphilis may be manifested by a great variety of apparently unrelated clinical symptoms Although isolated lesions such as iritis or periostitis may not in themselves suggest the diagnosis the recognition of other symptoms such as sore throat lymphadenopathy or skin lesions will often make the diagnosis of secondary syphilis obvious Whenever secondary syphilis is suspected blood should be taken for a serologic test This will be positive in practically 100 per cent of the cases Conversely if the serologic test is negative (and technical errors excluded) secondary syphilis can be ruled out

INFECTIOUSNESS AND EPIDEMIOLOGY

Syphilis is most infectious during the primary and secondary stages when there are moist skin or mucosal lesions The genital condylomas and the oral mucosal lesions contain large numbers of spirochetes and are more infectious than the dry skin lesions The transmission of the disease by individuals or marital partners who deny having had open lesions is probably by way of small mucosal lesions which appear during the recurrent episodes of spirochetemia Some secretions such as saliva and semen are frequently in contact with infectious mucosal lesions and may thus contain *T pallidum* The blood of patients ...

develops to his own infection and the immunity he develops to reinfection

Practically every patient with syphilis develops some resistance to his own infection The degree of immunity determines whether the patient will achieve a spontaneous cure the disease will remain latent or late complications will develop The factors responsible for the development of this type of immunity and the destruction of spirochetes are largely unknown The serum of experimentally infected animals and patients with syphilis contains antibodies which immobilize and render noninfectious virulent strains of *T pallidum* These antibodies can be demonstrated in vitro by means of the *T pallidum* immobilization (TPI) test developed by Nelson In humans this immobilizing antibody appears during the early stages of syphilis and will usually persist indefinitely unless early adequate treatment for syphilis is instituted The antibody is not present in the serum of normal persons nor in those with nonspirochetal diseases but it occurs in the serum of patients with various treponematoses such as bejel yaws and pinta The exact relationship between this antibody and the development of immunity has not yet been determined

Humoral antibodies in syphilis have also been demonstrated by newer techniques such as the *T pallidum* immune adherence (TPIA) *T pallidum* agglutination (TPA) and *T pallidum* complement fixation (TPCF) tests These procedures for detecting syphilitic antibodies are still in the experimental stage

Apparently the outcome of the syphilitic infection is influenced to some extent by the sex and race of the individual Neurosyphilis for example occurs more frequently in men than in women and in a higher proportion of white individuals than Negroes Bone and cardiovascular syphilis are more common in Negroes

Immunity to reinfection develops soon after the onset of the disease In animals immunity has been found to appear within 3 weeks after the initial infection and to increase progressively during a period of 6 months In humans reinoculation usually results in a chancre if carried out within 15 days after the appearance of the primary lesion of the initial infection Later than this a chancre seldom develops but this resistance is relative

Adequate treatment of patients with early syphilis may abort the development of immunity and reinfections can occur If treatment is delayed until after this period immunity to reinfection becomes established and may remain throughout the life time of the individual

If inadequate treatment is given during early syphilis and complete destruction of the patient s spirochetes is not obtained redissemination of the organisms may occur and produce infectious skin and mucosal lesions This is the basis for the statement that poor treatment is worse than none at all Once the patient has developed immunity to his own infection (usually within 4 years after the onset of the disease) inadequate treatment does not result in redissemination of organisms

CLINICAL MANIFESTATIONS OF EARLY ACQUIRED SYPHILIS

Primary Stage The period of incubation may vary from 10 to 90 days The typical chancre is a solitary indurated nonpainful ulceration which heals slowly with scar formation It is often accompanied by painless enlargement of the regional lymph nodes the *satellite bubo* It must be emphasized that primary syphilis is often atypical and may be manifested by small multiple or painful lesions which resemble many other conditions Because of the frequent atypical appearance of the chancre the clinical diagnosis or exclusion of primary syphilis can never be relied upon and every genital lesion should have a dark field examination

Approximately 95 per cent of primary lesions are found on or near the genitalia In the male the chancre frequently appears on the coronal sulcus or on the prepuce Any part of the genitalia may be involved however Chancres of the external genitalia must be differentiated from chancroid granuloma inguinale lymphogranuloma venereum carcinoma and many other lesions which appear in this area In the female the primary lesion often appears on the labia and in the fourchette but the perineum pubis clitoris or urethra may be involved Chancres of the cervix are frequent and are often mistaken for nonspecific erosions About 5 per cent of primary lesions occur on the lips female breasts or in the mouth

In the diagnosis of primary syphilis serologic tests cannot be relied upon entirely since they are often negative in this stage of the disease Moreover a positive serologic reaction in a patient with a genital lesion may represent either latent infection associated with nonsyphilitic lesion or else a biologic false positive reaction caused by another disease (i e lymphogranuloma venereum or chancroid) For this reason a dark field examination is of greatest importance in the diagnosis of this stage of the disease and should be done on the first visit of every patient suspected of having primary syphilis If the initial dark field examination is negative material from the regional lymph nodes should be aspirated and examined All local medication as well as antibiotics with treponemicidal activity should be withheld but oral sulfonamides may be

administered during this period of time If the dark field examinations and serologic tests for syphilis are negative the serologic test should be repeated several times during the first 2 or 3 weeks and every few weeks thereafter for 3 months after the appearance of the lesion If the patient develops a positive serologic reaction in a high or rising titer (with or without evidence of secondary manifestations) then antisyphilitic therapy should be begun A single serologic test of low titer is not sufficient evidence for beginning antisyphilitic treatment if dark field examinations are negative Such tests should be confirmed several times for at least 2 or 3 weeks before treatment for syphilis is justified

Penicillin or other spirocheticidal drugs should not be given as a therapeutic test to patients suspected of having primary syphilis Healing of the genital lesion following such tests does not necessarily indicate the presence of syphilis since nonsyphilitic lesions sometimes heal spontaneously Biopsy of the genital lesions is often of value in the diagnosis of these patients

Secondary Stage The secondary stage of syphilis usually develops about 6 weeks after appearance of the chancre and is manifested by a generalized skin eruption and systemic symptoms Some patients exhibit secondary lesions without ever being aware of a primary others never develop secondary manifestations and enter the latent stage directly following the healing of the chancre

The appearance of the *cutaneous lesions* of secondary syphilis varies considerably and may be confused with many other skin eruptions The lesions most often found are papules maculopapules or follicular papules Occasionally annular pustular or rupial lesions occur Indeed almost any type of skin eruption may appear except a vesicular one The rash is usually widespread and frequently involves the palms soles and face in addition to the trunk and extremities The lesions are sometimes pruritic

The *mucous membranes* of the mouth and genitalia are often involved in secondary syphilis Syphilitic lesions of the mouth appear as painless superficial erosions on the buccal surfaces on the tongue or inside the lip When these lesions are covered with a thin grayish exudate they are known a *mucous patches* They contain a large number of spirochetes but may be very inconspicuous and the patient may not be aware of them Lesions of the palate and tonsillar area can cause a persistent *sore throat* So-called *split papules* are occasionally seen in secondary syphilis and may be mistaken for herpes benign fissures or the lesions of riboflavin deficiency

Syphilitic mucosal lesions of the genitalia or perineal regions often become hypertrophic and are called *condylomata lata* These lesions are broad flat wartlike excrescences which are found on the labia majora perineum and anal region They are highly infectious and should be differentiated from condylomata acuminata which are nonvenereal pedunculated lesions

Although the clinical findings of secondary syphilis are often confined to the skin and mucous membranes many patients will present evidence of *constitutional symptoms* and widespread spirochetal dissemination Malaise lassitude headaches fever and myalgia are often noted There may be a *generalized lymphadenopathy* Localized areas of *alopecia* also occur causing a "moth-eaten" appearance of the scalp

Approximately 4 per cent of patients with secondary syphilis have involvement of the eye usually *iritis* or *neuroretinitis*

Skeletal lesions occasionally occur in secondary syphilis and are manifested by localized areas of swelling and tenderness *Arthralgia* and *hydrarthrosis* also occur but changes in the joints cannot be detected by x ray examination An acute *nephrosis* with marked proteinuria edema and hypercholesteremia is sometimes seen in secondary syphilis Evidence of *central nervous system involvement* such as paralysis of the cranial nerves or meningitis may also appear in this stage of the disease

It is apparent from the above description that secondary syphilis may be manifested by a great variety of apparently unrelated clinical symptoms Although isolated lesions such as iritis or periostitis may not in themselves suggest the diagnosis the recognition of other symptoms such as sore throat lymphadenopathy or skin lesions will often make the diagnosis of secondary syphilis obvious Whenever secondary syphilis is suspected blood should be taken for a serologic test This will be positive in practically 100 per cent of the cases Conversely if the serologic test is negative (and technical errors excluded) secondary syphilis can be ruled out.

INFECTIOUSNESS AND EPIDEMIOLOGY

Syphilis is most infectious during the primary and secondary stages when there are moist skin or mucosal lesions The genital condylomas and the oral mucosal lesions contain large numbers of spirochetes and are more infectious than the dry skin lesions The transmission of the disease by individuals or marital partners who deny having had open lesions is probably by way of small mucosal lesions which appear during the recurrent episodes of spirochetemia Some secretions such as saliva and semen are frequently in contact with infectious mucosal lesions and may thus contain *T pallidum* The blood of patients with early syphilis has

been shown to contain spirochetes and should not be used for transfusion The serologic test is not always an indication of the infectiousness of the blood since transfusion syphilis can be transmitted from patients in the incubation period or in the seronegative primary stage of the disease The danger of *transmitting syphilis either by transfusion* or by direct contact is greatest in the first 4 years of the disease and is negligible after this period of time In pregnancy however the disease can apparently be transmitted to the fetus for as long as 10 years or more after the onset of the disease although the vast majority of congenital infections are acquired during the first 4 years of maternal infection

It is important that the physician make an effort to determine the source of infection of his patients with syphilis particularly those with primary and secondary manifestations It is equally important that the individuals to whom the patient may have transmitted the infection be located They should be followed with physical examinations and serologic tests for several months before being dismissed

LATENT SYPHILIS

Latent syphilis is that stage of the disease in which there are no clinical signs or symptoms of the infection Patients without signs or symptoms *but with abnormal spinal fluid findings have a much* more serious prognosis and are not regarded as having latent syphilis but are classified instead as having asymptomatic neurosyphilis

Latent syphilis is by far the most frequent type of syphilis Routine serologic testing is the only way in which the majority of patients with latent syph*ilis can be recognized*

Although the syphilitic infection is not clinically evident during the latent period it may be producing serious changes in the viscera Often the spirochete exists within the body throughout the entire lifetime of the host without producing any apparent effects upon health and longevity Most of the patients with late latent syphilis develop sufficient resistance to their infection to prevent late clinical manifestations

The diagnosis of latent syphilis is one of exclusion and a careful history and physical examination should be made for clinical evidence of this disease Since the diagnosis of latent syphilis is dependent upon the serologic test false positive reactions must be ruled out *Treponema pallidum* immobilization (TPI) tests or the newer *T pallidum* complement fixation test (TPCF) should probably be carried out routinely in patients with positive serologic tests in whom there is no history or clinical evidence of syphilis and in whom the diagnosis seems unlikely

CLINICAL MANIFESTATIONS OF LATE ACQUIRED SYPHILIS

Skin and Mucous Membranes Late syphilis of the skin may appear either as small nodules or ulcerating gummas The gumma begins as a pain*less subcutaneous tumor which gradually softens* and ruptures exuding a viscous gummy material Spirochetes are seldom found in these lesions The nodular form of late syphilis consists of slightly raised reddish brown lesions on the skin which often coalesce to form arciform or serpiginous configurations

Gummas also occur in the mucous membranes of the nose and throat and may produce painful destructive lesions in the palate and nasal septum

Skeletal System Late osseous syphilis often presents a difficult diagnostic problem The chief symptoms are pain tenderness and local warmth The bones usually involved are the skull and tibia although the clavicle humerus ribs and nasopalatine structures are sometimes affected

Syphilis of the skeletal system is often confused with other types of subacute or chronic osteomyelitis primary or secondary neoplasms or Paget s disease The diagnosis can usually be made by close correlation of the serologic clinical and roentgenographic findings In some instances biopsy may be necessary

The most common joint manifestation occurring in late syphilis is the *Charcot joint* This condition is not caused directly by *T pallidum* but develops as a consequence of destruction of the proprioceptive nerves in tabes dorsalis It also occurs in other neurologic disorders such as syringomyelia The Charcot joint is usually confined to a *single weight bearing joint such as the knee ankle or* hip and occasionally the spine It begins as a painless swelling of the joint and is later manifested by hypermobility and loss of contour The joint surface disintegrates so that fragments of bone and cartilage can be felt within the joint capsule Charcot joints often appear in arrested or "burnt out cases of tabes dorsalis—i e patients with normal blood and spinal fluid findings Antisyphilitic drugs are of little value in treatment and orthopedic measures are usually necessary

Liver In patients with late syphilis *the liver may* contain multiple minute gummatous lesions or several very large ones On healing these lesions produce scarring and contraction of the surface giving the liver the appearance of having several additional lobes—hence the name *hepar lobatum* The most common *finding on physical examination is a* large coarsely nodular irregular liver Ascites jaundice and splenomegaly are occasionally present The serologic test for syphilis is almost always positive Response to treatment is often dramatic

with rapid reduction in liver size and relief of symptoms

Stomach Late syphilis of the stomach consists of a diffuse granulomatous infiltration of the stomach wall or a localized annular constriction about the pyloric area Secondary ulceration and obstruction may occur so that differentiation from carcinoma by roentgenographic examination is often impossible Syphilis of the stomach may be suspected in young individuals on the basis of the roentgenographic appearance of the lesion and a positive serologic test but exploratory laparotomy is usually indicated to confirm the diagnosis

Larynx Syphilis of the larynx produces hoarseness without pain Laryngoscopic examination may reveal gummatous infiltration of the vocal cords with secondary ulceration The lesions may simulate carcinoma or tuberculosis and biopsy is necessary for differential diagnosis *Treatment* of this condition should be cautious since intensive therapy has been known to produce edema stridor and suffocation Patients with late syphilis may also develop hoarseness without pain as a result of recurrent nerve paralysis caused by aneurysm of the aorta

Kidney and Genitourinary Tract An acute nephrotic syndrome occasionally appears in early syphilis In late syphilis a specific type of interstitial nephritis may be present on postmortem examination without having produced a characteristic clinical picture Gumma of the kidney is rare but late syphilis of the bladder testes and penis is occasionally reported Paroxysmal hemoglobinuria is sometimes caused by syphilis It is discussed in another section (see p 1187)

In the female late syphilis rarely involves the internal genital organs but gummatous lesions sometimes appear in the breast

Involvement of the endocrine glands such as the adrenals thyroid and pituitary gland is also infrequent

Cardiovascular Syphilis Since cardiovascular syphilis is discussed fully elsewhere (p 1336) it will be mentioned only briefly at this point Cardiovascular syphilis is one of the most important of the late lesions of syphilis and probably accounts for the majority of deaths resulting from this disease It is much more common in men than in women and seems to be more frequent in Negroes than in whites It usually appears in the second to third decade after infection and may be associated with neurosyphilis and other late manifestations

The fundamental lesion of cardiovascular syphilis is *aortitis* *Treponema pallidum* causes destruction of the media fragmentation of the elastic material and eventual dilatation of the vessel The base of the aorta is often involved with dilatation of the valve ring and *aortic insufficiency* If the weakening is localized a saccular *aneurysm* may develop The intima of the aorta becomes thickened and occlusion of the orifices of the coronary arteries may occur A few cases of multiple gummas of the *myocardium* have been reported but the existence of a diffuse syphilitic myocarditis is a matter of controversy

Central Nervous System Neurosyphilis together with cardiovascular syphilis accounts for about 90 per cent of deaths caused by syphilis Although all the tissues of the central nervous system are invaded by the spirochetes the clinical symptoms may be arbitrarily divided into meningeal vascular and parenchymatous Meningeal and vascular symptoms usually develop early in the course of the disease whereas parenchymatous involvement as manifested by tabes dorsalis and paresis usually does not appear until 10 to 20 years after the primary infection Meningeal lesions are inflammatory and often reversible Parenchymatous lesions however are likely to be degenerative with irreversible damage The type of lesion which predominates the structures involved and the exact location of the lesion within the central nervous system are the three important factors which influence prognosis and response to treatment

Gummas of the brain and spinal cord are occasionally observed They produce symptoms similar to tumors of the central nervous system and differentiation is difficult

Asymptomatic Neurosyphilis Asymptomatic neurosyphilis is that stage of the disease in which an abnormal spinal fluid exists without clinical signs or symptoms to indicate that the function of the central nervous system has been affected

The outcome of asymptomatic neurosyphilis and the extent of the spinal fluid abnormalities appear to be definitely related since patients exhibiting marked changes are more likely to develop signs and symptoms Some workers believe that the activity of the neurosyphilitic process is related to the spinal fluid cell count and protein level The presence of a positive spinal fluid Wassermann reaction indicates that infection of the central nervous system has occurred the cells and protein indicate the activity of the condition This concept maintains that if the spinal fluid is inactive—i e if the cell count and protein are normal—the syphilitic infection in the central nervous system has been arrested and no further therapy is needed Although this concept is not completely accepted it seems to hold true in the majority of patients

The serologic reaction of the blood does not always parallel the spinal fluid findings Patients with previous treatment may have a negative blood test and a strongly positive spinal fluid This combination seldom occurs in untreated cases

If the spinal fluid is completely negative 5 years

after the onset of the disease it rarely if ever becomes positive again

Meningitis In a small number of patients involvement of the central *nervous system may* be manifested by an acute meningitis This condition usually appears within the first 2 years after the onset of syphilis It nearly always occurs in patients who have previously had inadequate therapy and may be associated with an infectious or mucocutaneous relapse

The symptoms usually consist of cranial nerve lesions delirium convulsions or signs of increased intracranial pressure *Papilledema* is frequently found in patients with syphilitic meningitis and these cases are often diagnosed erroneously as having *brain tumors*

The serologic test for syphilis and the spinal fluid Wassermann are usually strongly positive The spinal fluid may show a marked lymphocytosis counts as high as 2 000 cells per cu mm having been observed This condition is often confused with other forms of lymphocytic meningitis such as tuberculous or virus meningitis The immediate prognosis is good but the ultimate prognosis is much more serious If the patient does not receive *adequate treatment late manifestations* of neurosyphilis or paresis are likely to develop

Meningovascular Syphilis Meningovascular syphilis is usually manifested by signs of thrombosis of one or more of the branches of the cerebral or spinal arteries Since there is almost always some evidence of leptomeningitis the term meningovascular syphilis is used to describe these cases

The symptoms of this condition depend upon the location and size of the vessels involved Monoplegia or hemiplegia hemianesthesia aphasia or hemianopsia may occur Cranial nerve palsies are frequent and convulsions are often observed Syphilitic endarteritis may also involve the cerebellar vessels Patients with meningovascular syphilis sometimes develop psychotic behavior and differentiation from paresis is often difficult

In older patients it is often impossible to differentiate clinically between syphilitic vascular disease and a cerebral vascular accident of other etiology In such cases the blood and spinal fluid findings provide the only means of differentiation The blood serologic test is positive in the majority of patients with vascular neurosyphilis and the spinal fluid usually shows a moderate increase of cells and protein with a positive Wassermann reaction A diagnosis of meningovascular syphilis should not be made if the spinal fluid is normal

The vessels and meninges of the spinal cord undergo *changes* identical with those in the brain With thrombosis of the *anterior spinal artery* the patient may *suddenly* develop signs of an acute *transverse myelitis* with paraplegia loss of sensation and fecal or urinary incontinence Usually however meningovascular lesions of the spinal cord are insidious and produce chronic progressive paralyses and *sensory disturbances* A number of neurologic syndromes result from more or less localized spinal cord lesions syphilitic involvement of the pyramidal tract produces the so called *Erb s spastic spinal paraplegia* anterior horn cell degeneration causes a picture similar to *progressive muscular atrophy* while a single localized *gumma* may simulate cord tumor

The term *meningovascular syphilis* is also employed for a large group of patients with diverse signs and symptoms such as *epilepsy eighth nerve deafness* other cranial nerve lesions or chronic headaches Pupillary abnormalities are frequently present and may consist of a variety of changes such as miosis dilatation anisocoria fixed pupils or typical Argyll Robertson phenomena

Tabes Dorsalis (Locomotor Ataxia) Tabes dorsalis is a form of neurosyphilis in which there is selective degeneration in the posterior roots of the spinal nerves and the posterior columns of the spinal cord Microscopically the dorsal roots may appear completely demyelinated and there is marked loss of nerve fibers The posterior *columns* of the spinal cord also show a loss of myelin and degeneration of the axons Spirochetes are rarely found in these lesions In the majority of cases tabes appears 20 to 30 years after the initial infection It is found more commonly in men than in women

Patients with tabes frequently develop severe agonizing *shooting* or *lightning* pains in the legs Girdle pains also occur in tabetics along with paresthesias numbness and tingling of the trunk hands or feet Another type of severe pain occurs in attacks of *gastric crises* About 10 per cent of tabetic patients develop severe episodes of abdominal pain associated with nausea and vomiting These attacks may last for days resulting in dehydration and exhaustion Patients with gastric crises are sometimes diagnosed as having acute surgical conditions and unnecessary operations have been performed on these individuals

Ataxia is a major symptom in tabes and may be so severe that the patient is unable to walk or stand Some patients develop a typical tabetic gait which consists of slapping of the feet and walking on a broad base The ataxia is worse in the dark and the patient may sway or fall when standing with his eyes closed (Romberg s sign) The damage to the nerve fibers in the posterior columns not only results in ataxia but also produces loss of position sense and the patient does not know without visual assistance the exact position of his toes or feet Vibratory sensation in the legs is diminished or absent There may be diminution of deep pain

sensation to pressure on the testes or Achilles tendon and areas of hypesthesia may be present on the trunk or in the hands and feet The patella and Achilles tendon reflexes are sluggish or absent Patients with tabes often show evidence of hypotonia and hyperextensibility of the joints Degenerative lesions such as chronic nonhealing lesions of the skin and *Charcot joints* are also found

Involvement of the autonomic nervous system may occur in patients with tabes and *postural hypotension* is occasionally present Severe *paroxysmal hypertension* associated with gastric crises has also been observed and may simulate paroxysmal hypertension caused by pheochromocytoma

Urinary difficulties occur in approximately 50 to 60 per cent of patients with tabes These often appear early in the disease and consist of hesitancy or difficulty in starting micturition Later the patient develops complete loss of bladder sensation Patients with tabetic bladder often give no history of urinary symptoms and catheterization for residual urine should be done in all who have evidence of tabes *Impotence* and loss of sexual desire are frequently noted

Paralysis of the oculomotor nerves is common in tabes resulting in diplopia ptosis of the lids or ophthalmoplegia Pupillary abnormalities are also extremely common and may be manifested by the classic *Argyll Robertson phenomena* that is miosis reaction to accommodation but no reaction to light poor response to atropine and absence of cilio spinal reflex This condition must be differentiated from *Adie s pupil* which is usually unilateral is larger than the normal pupil and reacts slowly to both light and accommodation Patients with Adie s pupils may also have absent or diminished tendon reflexes

Atrophy of the optic nerve occurs in about 10 to 15 per cent of patients with tabes About 70 per cent of patients with untreated optic atrophy become blind in *3 years and 90 per cent in 5 years* On ophthalmoscopic examination the optic disk appears white and sharply defined The physiologic cup is prominent and the lamina cribrosa is abnormally conspicuous Visual field defects and diminution of vision may be present with only slight changes in the color of the disks To detect such cases of optic atrophy early careful perimetry and visual acuity examinations should be made in all cases of neurosyphilis Although improvement in vision is not to be expected in patients with optic atrophy arrest of the atrophic process can usually be obtained by penicillin therapy in patients with early involvement

In early cases of tabes the serologic test for syphilis is often strongly positive and the spinal fluid may show definite abnormalities such as increased cells and protein and a positive Wassermann In patients with long standing tabes however the blood and spinal fluid findings may be misleading Approximately one fourth of such patients have negative blood serologic tests while as many as 20 per cent have normal spinal fluids Tabes dorsalis must be differentiated from numerous other diseases of the spinal column such as cord tumor combined system disease and syringomyelia as well as various types of peripheral neuritis (particularly diabetic neuropathy) The response of tabes to treatment is often poor and symptoms may progress despite all forms of therapy

Paretic Neurosyphilis (Dementia Paralytica Paresis General Paralysis of the Insane) General paresis is a psychosis caused by extensive spirochetal invasion of the brain On histologic examination the most prominent feature is degeneration of the nerve cells Perivascular infiltration and endothelial proliferation of the small vessels is seen *Treponema pallidum* can be demonstrated in the cerebral cortex and other portions of the brain

Paretic neurosyphilis is more common in men than in women and usually develops between the ages of thirty five and fifty years The onset is most often insidious prodromal symptoms consist of headache insomnia difficulty in concentration and easy fatigability As the disease progresses a gradual change in personality takes place with increased irritability memory loss poor judgment lack of personal care and deviations in character These alterations may occur over a period of several months Many of them are noted by the patient s family only in retrospect and elicited only by close questioning The onset of paresis is sometimes sudden and may be ushered in by convulsions syncope or a cerebral vascular accident

The simple demented type of psychosis is the most common These patients show confusion apathy impaired memory and defects in judgment Memory is particularly poor for recent events They are often unable to concentrate on simple calculations and show little insight or concern about their illness The grandiose form of paresis is manifested by euphoria overactivity ideas of grandeur and megalomania Auditory and visual hallucinations are not common in these patients but delusions of wealth and prowess are frequent The type of psychosis that prevails in a given case depends to a great extent upon the preparetic personality of the individual As the disease progresses however the symptoms of euphoria paranoia or mania recede and simple deterioration and dementia become the outstanding features

Eventually the patients become completely bedridden and are unable to move and feed themselves

On neurologic examination these patients may present various motor disturbances such as *tremors* of the facial muscles tongue and outstretched

after the onset of the disease it rarely if ever becomes positive again

Meningitis In a small number of patients involvement of the central nervous system may be manifested by an acute meningitis This condition usually *appears within the first 2 years after the* onset of syphilis It nearly always occurs in patients who have previously had inadequate therapy and may be associated with an infectious or mucocutaneous relapse

The symptoms usually consist of cranial nerve lesions delirium convulsions or signs of increased intracranial pressure *Papilledema* is frequently found in patients with syphilitic meningitis and these cases are often diagnosed erroneously as having brain tumors

The serologic test for syphilis and the spinal fluid Wassermann *are usually strongly positive* The spinal fluid may show a marked lymphocytosis counts as high as 2 000 cells per cu mm having been observed This condition is often confused with other forms of lymphocytic meningitis such as tuberculous or virus meningitis The immediate prognosis is good but the ultimate prognosis is much more serious If the patient does not receive *adequate treatment late manifestations of neuro* syphilis or paresis are likely to develop

Meningovascular Syphilis Meningovascular syphilis is usually manifested by signs of thrombosis of one or more of the branches of the cerebral or spinal arteries Since there is almost always some evidence of leptomeningitis the term meningovascular syphilis is used to describe these cases

The symptoms of this condition depend upon the *location and size of the vessels involved* Monoplegia or hemiplegia hemianesthesia aphasia or hemianopsia may occur Cranial nerve palsies are frequent and convulsions are often observed Syphilitic endarteritis may also involve the cerebellar vessels Patients with meningovascular syphilis sometimes develop psychotic behavior and differentiation from paresis is often difficult

In older patients it is often impossible to differentiate clinically between syphilitic vascular disease and a cerebral vascular accident of other etiology In such cases the blood and spinal fluid findings provide the only means of differentiation The blood *serologic test is positive in the majority* of patients with vascular neurosyphilis and the spinal fluid usually shows a moderate increase of cells and protein with a positive Wassermann reaction A diagnosis of meningovascular syphilis should not be made if the spinal fluid is normal

The vessels and meninges of the spinal cord undergo changes identical with those in the brain With thrombosis of the anterior spinal artery the patient may suddenly develop *signs of an acute transverse myelitis* with paraplegia loss of sensation *and fecal or urinary incontinence Usually* however meningovascular lesions of the spinal cord are insidious and produce chronic progressive paralyses and sensory disturbances A number of neurologic syndromes result from more or less localized spinal cord lesions syphilitic involvement of the pyramidal tract produces the so called *Erbs spastic spinal paraplegia* anterior horn cell degeneration causes a picture similar to *progressive muscular atrophy* while a single localized *gumma* may simulate cord tumor

The term *meningovascular syphilis* is also employed for a large group of patients with diverse signs and symptoms such as *epilepsy eighth nerve deafness* other cranial nerve lesions or chronic headaches Pupillary abnormalities are frequently present and may consist of a variety of changes such as miosis dilatation anisocoria *fixed pupils* or typical Argyll Robertson phenomena

Tabes Dorsalis (Locomotor Ataxia) Tabes dorsalis is a form of neurosyphilis in which there *is selective degeneration in the posterior* roots of the spinal nerves and the posterior columns of the spinal cord Microscopically the dorsal roots may appear completely demyelinated and there is marked loss of nerve fibers The posterior columns of the spinal cord also show a loss of myelin and degeneration of the axons Spirochetes are rarely found in these lesions In the majority of cases tabes appears 20 to 30 years after the initial infection It is found more commonly in men than in women

Patients with tabes frequently develop severe agonizing *shooting* or *lightning* pains in the legs *Girdle pains also occur in tabetics along* with paresthesias numbness and tingling of the trunk hands or feet Another type of severe pain occurs in attacks of *gastric crises* About 10 per cent of tabetic patients develop severe episodes of abdominal pain associated with nausea and vomiting These attacks may last for days resulting in dehydration and exhaustion Patients with gastric crises are sometimes diagnosed as having acute surgical conditions and unnecessary operations have been performed on these individuals

Ataxia is a major symptom in tabes and may be so severe that the patient is unable to walk or *stand Some patients develop* a typical tabetic gait which consists of slapping of the feet and walking on a broad base The ataxia is worse in the dark and the patient may sway or fall when standing with his eyes closed (Rombergs sign) The damage to the nerve fibers in the posterior columns not only results in ataxia but also produces loss of position sense and the patient does not know without visual assistance the exact position of his toes or feet Vibratory sensation in the legs is diminished or absent There may be diminution of deep pain

ous modifications of flocculation tests for syphilis have been named after their originators (Kahn Eagle Mazzini Kline and Hinton) The complement fixation technique or Wassermann test employs the same type of antigen The Kolmer and Eagle modifications of the Wassermann technique are most commonly used in this country The VDRL (Venereal Disease Research Laboratory) test is a rapid slide flocculation technique employing cardiolipin antigen It has a high degree of sensitivity and specificity

Quantitative serologic tests for syphilis measure the quantity of reagin and are of value in the diagnosis and management of various stages of the disease A sharply rising titer is usually found in recently acquired syphilis while a stationary titer indicates an infection of some duration Quantitative serologic tests are also useful in the detection of false positive reactions A rapidly falling titer in the absence of therapy is evidence against the diagnosis of syphilis The height of the quantitative titer has no bearing on the prognosis or outcome of the disease The quantitative tests are also important in determining the results of therapy a continuing fall in titer indicates a satisfactory response

The presence of a negative reaction does not always exclude syphilis nor is a positive reaction always proof of the existence of the disease Serologic tests are negative in the incubation period of syphilis during the early weeks of the primary stage and in many of the late manifestations such as cardiovascular and neurosyphilis (tabes dorsalis in particular)

Biologic False Positive Serologic Tests for Syphilis Positive reactions appear in a great variety of illnesses and are due presumably to the appearance in the patient s serum of substances which act like reagin and give positive flocculation and complement fixation reactions for syphilis These reactions are usually transient but in some instances may be positive for months or years

Biologic false positive reactions are frequently observed in patients with vaccinia infectious mononucleosis malaria leprosy and upper respiratory diseases as well as in spirochetal infections such as yaws pinta and relapsing fever Other infections which are occasionally associated with false positive reactions are lymphogranuloma venereum chancroid measles chicken pox atypical pneumonia infectious hepatitis rat bite fever and disseminated lupus erythematosus In fact any febrile disease or immunization is a potential cause of false positive tests There is evidence that individuals with biologic false positive reactions of long duration may have serious illnesses such as collagen disorders sarcoid or lymphomas

The *Treponema pallidum* immobilizing (TPI) test of Nelson and the newer *T pallidum* complement fixation (TPCF) test are often of considerable aid in the diagnosis of false positive reactions These tests are almost always positive in late syphilis A negative TPI or TPCF test is therefore of value in excluding the diagnosis of syphilis A positive test on the other hand indicates the existence of a syphilitic infection even if the standard serologic tests are negative In most cases the false positive reaction will become negative within 6 months If the patient continues to show a positive serologic test and if the adjunct procedures do not indicate a false positive reaction antisyphilitic therapy should be instituted If the patient becomes pregnant or is to be married immediate treatment is indicated

Seroresistance In many patients with syphilis the serologic test remains positive despite prolonged intensive therapy These patients are called seroresistant or Wassermann fast One of the aims of therapy in early syphilis (particularly during the first 2 years of the disease) is to procure and maintain a negative serologic reaction In late syphilis however seroresistance is of little clinical importance and has no relationship to the outcome of the disease

In most patients with early syphilis the serologic test becomes negative within 6 months after beginning therapy Occasionally the titer of the serologic reaction falls very slowly and the tests remain positive in low titer (i e less than 4 dilution) for as long as 1 to 2 years In some patients with early syphilis there is very little serologic response to treatment and the titer remains high for 6 to 9 months or more This type of seroresistance is usually followed by clinical relapse and these patients should be re treated

Neurosyphilis is frequently associated with seroresistance in both early and late cases and the spinal fluid should be examined in every patient with a persistently positive serologic reaction

The seroresistant patient is often discouraged over the failure to reverse the serologic test and becomes deeply concerned for fear that the infection is not arrested In addition he may be embarrassed in applying for a marriage license or employment when blood tests are a part of the premarital or preemployment examination The physician should make every effort to reassure such patients that the outcome of the disease is not related to the persistence of a positive serologic test Seroresistance should not be an obstacle to marriage

Spinal Fluid Tests The spinal fluid must be examined in every patient with syphilis This is the only method of detecting involvement of the central nervous system in the asymptomatic stage of determining the efficacy of treatment and of confirming the diagnosis of symptomatic neurosyphilis

hands The patient s handwriting is altered because of the tremors and incoordination The speech becomes slurred and test phrases are mispronounced Pupillary abnormalities are common and deep reflexes are usually exaggerated Some patients with paresis also have signs and symptoms of tabes—i e, *taboparesis*

The demented form of paresis must be differentiated from senile dementia and Alzheimer s disease The manic and paranoic types must be distinguished from manic depressive psychoses and schizophrenia In the early stages of paresis differentiation from neurasthenia is sometimes difficult and spinal fluid examination may be the only means of diagnosis

The spinal fluid in general paresis shows marked *changes with increased cells and protein positive* Wassermann test and first zone colloidal reaction The diagnosis of paresis should never be made in the presence of a normal spinal fluid a positive spinal fluid is present in 100 per cent of untreated cases

The course of untreated paresis is progressive and death usually occurs within a few years after the onset of symptoms The prognosis improves considerably with therapy but the chances for complete recovery are at best about 50 to 60 per cent

SYPHILIS IN PREGNANCY

Syphilis in pregnancy is a special problem because the fetus becomes infected after the fifth month of pregnancy by passage of *T pallidum* through the placenta This usually occurs in women with early untreated syphilis but is sometimes observed in late syphilis Pregnancy complicated by syphilis may terminate in a spontaneous abortion a stillborn infant or a premature or full term infected child The maternal infection however *becomes attenuated as the duration of the disease* increases and the chances of the fetus being infected are less with each succeeding pregnancy

Pregnancy is believed to have a beneficial influence upon the course of the syphilitic infection and late manifestations of the disease seem to occur less frequently in multiparous women than in others A serologic test for syphilis should be taken routinely at the first prenatal visit of every pregnant woman The early recognition of syphilis in pregnancy followed by adequate treatment will prevent congenital syphilis in almost every instance

CONGENITAL SYPHILIS

Infantile congenital syphilis is often an overwhelming infection such infants are severely ill malnourished and dehydrated The most common manifestations of the disease in infants are skin lesions fissures condylomas persistent rhinitis tenderness over the long bones and pseudoparalysis

The diagnosis of syphilis in the infant is best established by dark field demonstration of *T pallidum* from the cutaneous or mucosal lesions A positive serologic test in the first two months of life does not always indicate syphilis in the infant since reacting substances may have been transferred from the maternal circulation A very high titer of the serologic reaction or a steady rise in titer however is indicative of congenital syphilis Roentgenographic examination of the long bones may show characteristic areas of bone destruction and *osteochondritis*

Late congenital syphilis frequently manifests itself *in the* second decade with signs of central nervous system involvement such as eighth nerve deafness optic atrophy and *juvenile paresis* The prognosis of congenital neurosyphilis is serious these patients commonly show little response to treatment Cardiovascular syphilis is rare in the congenital infection

Patients with late congenital syphilis often exhibit typical stigmas such as hypoplasia wide spacing and notching of the central incisors (*Hutchinson teeth*) frontal bossing a highly arched palate and *saber shins* The first permanent molar is also frequently affected in congenital syphilis and shows a characteristic appearance with several small atrophic cusps on the occlusal surface This is known as a mulberry molar *Interstitial keratitis* a frequent complication usually appears in the second decade It is characterized by pain lacrimation circumcorneal injection and corneal opacity The response to therapy is poor and serious impairment of vision often results Occasionally hydrarthrosis of the knee joint (*Clutton s synovitis*) is associated with interstitial keratitis

LABORATORY DIAGNOSIS

Dark field demonstration of *T pallidum* is most useful in the early stages of syphilis It should be employed routinely on every genital lesion and on all cutaneous and mucosal lesions suspected of being syphilitic In the hands of a competent microscopist dark field examination is reliable and establishes without doubt the diagnosis and stage of the infection

Serologic Tests Serologic tests for syphilis (STS) *are the most commonly used diagnostic procedures* In latent syphilis they are the only means by which the diagnosis can be made The serologic tests are based upon the presence of an antibodylike substance (sometimes called *reagin*) which appears in the patient s serum soon after the onset of the disease Syphilitic serum reacts with an antigen made from an alcoholic extract of beef heart Vari

other course of therapy with penicillin is indicated

Serologic tests should be taken at 3 month intervals during the second year after treatment and at 6-month intervals during the third fourth and fifth years If at the end of 5 years the patient has no clinical evidence of syphilis and has a normal blood and spinal fluid he may be considered completely cured

A spinal fluid examination should be performed 6 months after the completion of treatment for early syphilis If it is normal at this time and if the patient continues to show no evidence of clinical or serologic relapse it need not be repeated until approximately two years following treatment Patients having positive spinal fluid tests for syphilis 6 months or more after treatment for early syphilis should be re treated

Relapse and Reinfection Evidence of relapse in early syphilis may occur as early as 4 weeks or as late as 2 years after treatment

The prognosis of relapsing syphilis is more serious than the initial infection and such patients should be re treated with twice the original dose of penicillin given over a longer period of time Many patients with recurrent syphilis actually have a new infection rather than a relapse of their original infection Although various criteria have been set up to distinguish relapse from reinfection differentiation is often impossible

Syphilis in Pregnancy Congenital syphilis can be prevented by proper treatment of syphilis in pregnancy Although women with syphilis of many years duration are not likely to bear syphilitic children further treatment of such patients during pregnancy is recommended Although treatment with penicillin is of considerable value when given during the last months of pregnancy it is best given before the fetus becomes grossly infected i e before the last trimester

All patients treated for syphilis in pregnancy should be observed very closely and quantitative serologic tests for syphilis taken at least every month Re treatment during pregnancy is indicated if there is a rise in serologic titer following therapy if a definite decrease in titer fails to occur in patients with early syphilis or if the patient develops recurrent syphilitic lesions A positive serologic test at the time of delivery does not necessarily indicate that treatment has been inadequate The child born of a mother treated for syphilis should have a serologic test every 2 to 4 weeks until it is at least six months of age Once the woman has received adequate amounts of penicillin for syphilis it is not necessary to re treat her during succeeding pregnancies if the titer of the serologic test is negative or remains low (less than 1 4)

Congenital Syphilis Infants with congenital syphilis should receive careful supportive care and adequate nutrition in addition to antisyphilitic treatment Penicillin is very effective a total dosage of 200 000 units per kg body weight given in equally divided amounts every 3 hr for 7 to 10 days is adequate Although the use of procaine penicillin in a large series of these cases has not been reported this type of penicillin should also give satisfactory results Doses of 150 000 units of procaine penicillin in aqueous solution given every day for eight injections are recommended Follow up blood tests and the indications for re treatment in early congenital syphilis are the same as in early acquired syphilis

Treatment of interstitial keratitis is not altogether satisfactory Penicillin therapy is recommended but it does not always result in reduction of the inflammation or clearing of the corneal opacities Occasionally interstitial keratitis appears for the first time during or immediately after what appear to be adequate dosages of penicillin It seems probable that this ocular manifestation represents a type of hypersensitivity phenomenon Cortisone in aqueous suspension (5 mg per ml) or in ointment form should be applied to the involved eye every few hours day and night for several weeks The inflammatory reaction often recurs however after the drug is discontinued and repeated courses may be necessary until spontaneous regression of the condition appears Hydrarthrosis (Clutton s synovitis) responds slowly to penicillin therapy

Late Syphilis *Latent Stage* The chief purpose in treating late latent syphilis is to prevent the development of gummatous lesions and cardiovascular syphilis Patients with late latent syphilis have negative spinal fluids and rarely if ever develop neurosyphilis

Penicillin has not been evaluated in late latent syphilis Since the prognosis of this stage of the disease is so good and since the drug is known to be effective in both early and late symptomatic syphilis it is presumed to be of value in patients with latent infection The treatment schedules suggested for early syphilis employing 4 to 6 million units of penicillin are recommended Failure of the serologic test to revert to negative after adequate treatment—i e *seroresistance*—is not necessarily a forerunner of late complications Once the patient with late syphilis has had adequate treatment additional penicillin therapy will not contribute significantly toward reversal of the blood test

Skin Bones and Viscera Gummatous lesions of the skin mucous membranes bones and viscera usually respond promptly to penicillin therapy The recommended total dosage of penicillin is greater than that employed in early syphilis and should be approximately 10 million units This can be administered as 900 000 units of procaine penicillin given every 48 hr for 12 injections The posttreatment

The spinal fluid cell count should be done within an hour after the fluid is withdrawn A count of more than 8 lymphocytes per cubic millimeter is usually considered abnormal Even a small amount of blood in the spinal fluid will affect the accuracy of the various examinations A quantitative de*termination of the spinal fluid protein should be* done in every case

Complement fixation tests for syphilis are generally regarded as being more sensitive than flocculation tests for examination of spinal fluid The spinal fluid of patients with neurosyphilis has been found to contain immobilizing antibodies for *T pallidum*

The spinal fluid may also show biologic false positive complement fixation or flocculation reactions This may be caused by a bloody tap or any condition which produces an increased protein in the spinal fluid Brain tumor bacterial or virus meningitis encephalitis or subarachnoid hemorrhage can produce a false positive test for syphilis in either syphilitic or nonsyphilitic patients

The value of colloidal precipitation tests (gold and *mastic reactions) has been overemphasized in* the diagnosis of neurosyphilis The zone of precipitation or the shape of the colloidal curve has *little* diagnostic significance

Biopsy Biopsy is a valuable diagnostic procedure especially for cutaneous lesions In late syphilis involving the lymph nodes testes or larynx it is indispensable

TREATMENT

In patients with early syphilis adequate treatment can produce an absolute or biologic cure with complete healing of lesions and reversal of serologic tests and spinal fluid findings These patients become entirely well are not infectious and do not develop any of the late manifestations of the disease

Treatment of late syphilis may not achieve these goals Despite long and vigorous therapy the serologic tests in late syphilis often remain positive Late syphilitic lesions are often associated with permanent damage and treatment may produce little or no return of function

Early Syphilis In 1943 penicillin was found to be effective in the treatment of syphilis The use of arsenicals bismuth or mercurials is rarely if ever indicated Other antibiotics such as Chloromycetin chlortetracycline and oxytetracycline have treponemicidal activity and produce healing of both early and late syphilitic lesions The ultimate place of these drugs in the treatment of syphilis has not yet been established They have the possible advantage of oral administration but are probably not as effective as penicillin and are somewhat more toxic Erythromycin and tetracycline have also been shown to have some treponemicidal action

Procaine penicillin and benzathine penicillin G have generally replaced crystalline penicillin in aqueous solution except perhaps in the very serious or far advanced stages of syphilitic infection The minimal effective total dosage of penicillin has been found to be approximately 2 4 million units Increasing the total amount of penicillin from 2 4 to 9 6 million units does not decrease the failure rate in early syphilis

The total dosage of depot penicillin usually prescribed is approximately 4 to 6 million units given over a period of 8 to 12 days This schedule will produce satisfactory results in about 90 per cent of patients The remaining 10 per cent will show clinical or laboratory changes of either a relapse or reinfection Benzathine penicillin G has also been found to be effective in early syphilis when given as a single injection of 2 4 million units or in 2 or 3 weekly doses It has the advantage from the public health standpoint of completing treatment *in a minimum period of time but is not recom*mended as a routine method of treatment Oral penicillin products are not recommended for the *treatment of syphilis The other antibiotics with* treponemicidal activity should be used only in patients in whom penicillin is contraindicated

Jarisch Herxheimer Reaction Within a few hours after the first injection of either an arsenical or penicillin about 50 per cent of patients with early syphilis experience fever malaise headache myalgia and a flare up of cutaneous lesions This is presumed to be caused by release of breakdown products of spirochetes following the injection of treponemicidal agents In early syphilis *these symp-*toms disappear within several hours and leave no permanent tissue damage In late syphilis such reactions can be disastrous if the lesions are located in such areas as the ostiums of the coronary arteries the wall of an aneurysm or the central nervous system

Posttreatment Observation After completing treatment patients should return every month during the first year for quantitative serologic tests and examination for relapsing lesions If the patient develops a recurrence of syphilitic lesions or evidence of neurosyphilis or if there is a birth of a syphilitic child re treatment is necessary If the serologic test in patients with early syphilis shows no appreciable decrease within 6 months or if the titer is elevated (arbitrarily a dilution of 1 4 or higher) 1 year after completion of therapy further treatment is indicated A positive reaction in any dilution 18 months or more after completion of treatment of primary or secondary syphilis should be considered as evidence of treatment failure, and an

Careful neuropsychiatric and spinal fluid observations should be made following treatment of all patients with neurosyphilis These should be done every 4 months during the first year twice during the second year and once a year thereafter or until the spinal fluid is completely negative and permanent regression of symptoms seems apparent In late neurosyphilis the spinal fluid Wassermann often remains positive for many years despite repeated courses of chemotherapy or fever this does not in itself indicate progression or relapse of the neurosyphilitic process

Herxheimer Reactions in Late Syphilis Exacerbations of late syphilitic lesions are not infrequently observed following the initial administration of arsenicals or penicillin Approximately one half the patients treated for paresis become temporarily worse and show increased agitation and mental confusion during the first 24 hr of penicillin treatment Other manifestations of Herxheimer reaction such as myelitis convulsions and exacerbation of lightning pains have been reported

There have been very few cases in which penicillin therapy has appeared to produce an acute exacerbation of clinical manifestations of cardiovascular syphilis Neither the use of small initial doses of penicillin nor preparatory treatment with bismuth seems indicated in an attempt to prevent Herxheimer effects

Effect of Penicillin and Other Antibiotics When Used for Other Diseases The widespread use of penicillin and antibiotics with treponemicidal properties in the treatment of various other infections has created confusion in the diagnosis and management of syphilis This is particularly true when gonorrhea is treated Patients with gonorrhea may have acquired syphilis simultaneously Although there is reason to believe that the use of penicillin and perhaps the other antibiotics frequently abort the syphilitic infection completely they may at times only delay the appearance of the lesions or prevent their development For these reasons it is recommended that all persons with gonorrhea treated with penicillin or the other spirocheticidal antibiotics should have serologic tests for syphilis at monthly intervals for at least 4 months The appearance of fever several hours after the administration of penicillin for gonorrhea is suggestive of a Herxheimer reaction and the presence of syphilis

The management of patients with positive serologic tests who have had previous penicillin therapy for other nonrelated infections is sometimes difficult If syphilitic infection is thought to be present the decision as to further therapy should be based upon the amount of penicillin already administered the type and duration of syphilitic infection the result of the spinal fluid examination and the titer of the serologic test

PROPHYLAXIS

Syphilis and the other venereal diseases can be prevented in most instances by the proper prophylactic measures during and following sexual intercourse Protection from contact with infectious genital lesions can be obtained to some degree by the use of a condom The danger of infection can also be reduced if the genitalia are washed thoroughly with soap and water immediately after exposure Although ointments containing various treponemicidal substances have been employed for many years as local prophylactic agents the use of such compounds is no longer recommended In small series of cases penicillin has been shown to prevent infection in individuals who are known to have been sexually exposed to patients with primary or secondary syphilis The use of penicillin in these cases is justified not only as an attempt to abort the infection in the exposed individual but also to prevent reinfection of the original patient who often maintains sexual relations with the contact despite instructions to the contrary

Procaine penicillin or benzathine penicillin G in doses of 1 2 million units should be given soon after exposure to persons who have had sexual contact with known or suspected cases of infectious syphilis The administration of penicillin as a routine prophylactic measure following every extramarital sexual exposure is neither practical nor advisable Persons receiving prophylactic treatment should be kept under observation if possible and should have repeated serologic tests for at least 6 months

The prophylactic treatment of nurses physicians or laboratory workers accidentally exposed to or inoculated with infectious material will depend largely upon the risk of infection in the individual case Another indication for prophylactic treatment is in pregnant women who are sexually exposed to infectious patients A full course of penicillin treatment in these cases is indicated in an effort to prevent fetal infection

PSYCHOTHERAPY

There is still considerable stigma and psychologic trauma attached to the diagnosis of syphilis and proper treatment requires more than the mere administration of chemotherapeutic agents The physician must be aware of the sociologic and psychologic aspects of this disease Patients often have a sense of shame and guilt and some of them postpone or discontinue medical care Others develop serious anxiety states and return to the physician repeatedly for reassurance that the disease has been arrested Some individuals develop syphilophobia as a result of having heard or read of the serious effects of the disease The physician should

observations and indications for re treatment of these patients are the same as those recommended above A high percentage of patients with late syphilitic lesions have abnormal spinal fluid findings and a lumbar puncture is indicated in every patient before treatment is instituted

Cardiovascular Syphilis The value of antisyphilitic therapy in late cardiovascular syphilis is difficult to determine Many syphilologists believe that treatment does not delay the ultimate development of myocardial failure or aneurysmal rupture Treatment appears to be of some value however in early aortic insufficiency uncomplicated aortitis or small asymptomatic aneurysms The risk of a serious Herxheimer reaction following initiation of penicillin treatment of these cases has been found to be minimal Preparatory bismuth therapy is probably of little value in preventing this type of reaction and most workers begin treatment with penicillin The total dosage is 10 to 15 million units of penicillin given in schedules similar to those recommended for gummatous lesions As in other types of late syphilis the serologic test often remains positive after therapy Proper management of congestive failure and restriction of physical activity of these patients is of paramount importance

Neurosyphilis The results of treatment of neurosyphilis depend largely upon the type and duration of the neuropathologic process If the predominant lesion of the central nervous system is degenerative as in tabes and optic atrophy little response to any form of treatment can be expected If the tissue reaction is chiefly inflammatory as in syphilitic meningitis rapid and almost complete return of function will occur

Fever therapy is rarely used at present even though there is evidence to indicate that its use in combination with penicillin may be more effective than penicillin alone in the treatment of selected patients with paresis optic atrophy and taboparesis

Penicillin treatment of neurosyphilis is often followed by dramatic clinical response with prompt and favorable changes in the spinal fluid Shortly after penicillin therapy there is a rapid reduction in the spinal fluid cell count and protein The spinal fluid Wassermann reaction however may not become negative for 5 years or more Penicillin produced normal spinal fluid cell counts in 85 to 90 per cent of patients treated for various types of neurosyphilis The remaining 10 to 15 per cent showed abnormal spinal fluid cell counts 6 to 12 months following treatment and were considered *treatment failures*

It is generally agreed that the response of the spinal fluid tests following penicillin is as good as that obtained with fever therapy in patients with optic atrophy paresis taboparesis and eighth nerve deafness Penicillin alone is recommended as the initial form of treatment in these cases and combined fever therapy and penicillin should be given in patients in whom re treatment is required

Penicillin alone is also the treatment of choice in patients with asymptomatic neurosyphilis syphilitic meningitis and meningovascular syphilis and in those with irreversible manifestations such as fixed pupils and Charcot joints The optimum dosage schedule has not been definitely established but doses of 10 to 15 million units are usually recommended either as the aqueous solution 100 000 units every 3 hr or as procaine penicillin in aqueous suspension 900 000 units daily

Treatment of the tabetic bladder may be very discouraging Drugs such as Mecholyl chloride and ergotamine have been employed to increase bladder tone and contraction but the results are variable In early cases the patient can be trained to micturate at regular intervals and empty the bladder by pressure on the lower abdomen In late cases surgical procedures (transurethral resection of the vesical neck suprapubic cystotomy) may be necessary Urinary tract infection should be prevented and instrumentation avoided as much as possible Charcot joints are rarely improved by antisyphilitic therapy and special orthopedic treatment is necessary The management of patients with gastric crises is sometimes very difficult In the acute attack the patient should be heavily sedated Morphine should be avoided Large doses of atropine are said to be of value in relieving the symptoms of gastric crises

In most cases of advanced optic atrophy the use of penicillin or fever alone or in combination does not prevent the development of blindness Patients with optic atrophy should be admitted to the hospital and given penicillin in aqueous solution 200 000 units every 4 hr for 13 to 17 days for a total dosage of 15 to 20 million units Re treatment with combined fever and penicillin is advised if there is definite evidence of progression

The relative value of penicillin and fever therapy in paresis has not yet been definitely determined Penicillin alone often results in marked improvement of tremors and speech and writing defects It has been reported to produce entirely satisfactory results in about 20 per cent and significant improvement in an additional 35 per cent of a large series of patients with paresis treated in a general hospital Large amounts of penicillin—15 to 20 million units in aqueous solution—should be given in schedules similar to that recommended for optic atrophy If there is no definite improvement in the paretic manifestations or if relapse occurs following an initial response treatment with combined penicillin and fever therapy is indicated In general such cases respond poorly to the second course of treatment

yaw The lesions of yaws often appear on the soles of the feet and produce painful ulcerations socalled crab yaws"

After several years late destructive lesions may appear in the skin and bones Periostitis and osteitis are found in the bones of the hands arms and legs producing characteristic dactylitis and "saber shins" Destructive lesions appear about the nose and result in severe ulcerative areas (*gangosa*) Proliferative exostoses develop in the nasal portion of the maxillary bones this is known as *goundou* Juxtaarticular nodules are also seen in the late stage of the disease Involvement of the aorta and the central nervous system has been reported but these complications are rare

Diagnosis The diagnosis of yaws can often be made on the appearance of the generalized skin eruption alone but *T pertenue* is easily demonstrated in the lesions The Wassermann and flocculation tests for syphilis are usually positive The lesions of yaws may be confused with those of leishmaniasis leprosy and tuberculosis It is often impossible to differentiate between late lesions of yaws and late gummatous syphilis

Treatment Penicillin has become the drug of choice in the treatment of yaws A single or a few injections of 1 2 million units of procaine penicillin have resulted in cure or marked improvement in more than 90 per cent of patients Benzathine penicillin G has been found to be equally effective Preliminary studies with chlortetracycline chloramphenicol and oxytetracycline indicate that these antibiotics are also of value in the management of this condition

155 PINTA

Albert Heyman

Definition Pinta is an infectious disease of the skin caused by *Treponema carateum* It is characterized by an initial papular lesion of the skin followed by depigmented areas on the extremities and hyperkeratosis on the soles and palms The disease is also known as *mal del pinto azul* and *carate* Pinta is found almost entirely in the Western Hemisphere and is especially prevalent in Mexico and Colombia

Etiology *Treponema carateum* the etiologic agent of pinta is morphologically indistinguishable from *Treponema pallidum* The exact relationship of this disease to other treponematoses (syphilis yaws and bejel) has not been definitely determined and there are many similarities in the clinical manifestations of these infections Pinta is usually transmitted from person to person by direct contact It may also be spread by an insect vector

Manifestations The primary lesion of pinta appears after an incubation period of 7 to 20 days as a nonulcerative papule at the site of infection This is followed 5 to 18 months later by a secondary eruption characterized by flat erythematous and hyperpigmented lesions called *pintids* Late lesions develop after several years and appear as vitiligoid slate blue or variously colored patches of the skin The hands wrists knees and ankles are commonly involved and hyperkeratoses of the palms and soles are also seen Aortitis and spinal fluid abnormalities similar to those found in neurosyphilis have been observed in some pinta patients The Wassermann reaction of the blood and flocculation tests for syphilis are usually positive in the late stages of the disease Eosinophilia is often present

Treatment A single injection of 1 2 million units of procaine penicillin or benzathine penicillin G produces rapid disappearance of the *T carateum* from the lesions of pinta and a decline in serologic titer It is the treatment of choice in this disease and is more effective than chlortetracycline chloramphenicol or oxytetracycline

156 LEPTOSPIRAL INFECTIONS

Paul B Beeson

Etiology and Epidemiology The leptospirae are delicate tightly coiled spirochetes many of which

make every effort to relieve these patients of their anxiety by correcting mistaken ideas regarding the infection and by emphasizing the good prognosis whenever possible His attitude toward the patient should be free of censure

Upon learning the diagnosis many patients either condemn their marital partners and threaten divorce or separation or else refuse to impart the information to their spouse The physician should not enter into the moral aspects of the disease but should make certain that the marital partners of patients with infectious syphilis are examined at regular intervals for evidence of the disease

154 YAWS

Albert Heyman

Definition Yaws is an infectious tropical disease caused by the *Treponema pertenue* It is characterized by a primary cutaneous lesion which is followed by a granulomatous skin eruption and in some instances by late destructive lesions of the skin and bones The disease is also known as *frambesia pian bouba* and *parangi*

Etiology The etiologic agent of yaws the *T pertenue* is morphologically indistinguishable from *Treponema pallidum* it further resembles the spirochete of syphilis as it produces a positive reaction with the Wassermann and flocculation tests for syphilis and is also susceptible to arsenicals bismuth and penicillin Cross immunity between the two diseases has been observed in both man and experimental animals There has been considerable controversy as to whether the two diseases were at one time identical and have been modified over the years by climate race and other factors

Epidemiology Yaws is confined entirely to the tropics and is prevalent in the West Indies South Pacific islands equatorial Africa and South America The disease is usually acquired before puberty and is spread by direct contact with open lesions containing the spirochete Transmission of the disease occurs rarely by sexual contact Certain species of flies are also thought to be vectors of this infection The disease is more common in natives with poor personal hygiene

Manifestations Following an average incubation period of 3 to 4 weeks a primary lesion the *mother yaw* appears at the site of inoculation This is almost invariably extragenital and usually occurs on the legs This lesion is a granuloma which later ulcerates and heals with scar formation About 6 to 12 weeks after the appearance of the lesion a generalized eruption develops consisting of large papules or granulomas on the face neck extremities and buttocks These lesions often occur about the mucocutaneous junctions such as the mouth nose and rectum and resemble condylomas of secondary syphilis They heal slowly but relapses may occur months or years after the onset of the initial

mon in Weil's disease being reported in about 20 per cent of cases They usually take the form of recrudescence of fever during the second week together with muscle pain and headache The duration of fever in relapses is usually short i e 2 to 5 days Severe hepatic or renal involvement is rare during relapses

Laboratory Findings The blood leukocyte count is nearly always elevated ranging from 12 000 to 25 000 cells per cubic millimeter The platelet and prothrombin content of the blood may be reduced though seldom is either of these so reduced as to be a likely cause of the hemorrhagic tendency In the majority of cases the bilirubin content of the plasma is increased and bilirubin appears in the urine The stools are seldom acholic however Disturbed liver function may be manifested by positive cephalin flocculation and an elevated thymol turbidity reading In patients who have leptospiral nephritis there may be oliguria hematuria proteinuria and cylindruria and elevation of the blood nonprotein nitrogen Examination of the spinal fluid reveals abnormal findings in 85 to 90 per cent of cases the commonest of these being increase in number of cells—i e from 10 to 250 per cubic millimeter the majority being mononuclear Xanthochromia of the spinal fluid is usually present in patients with clinical jaundice

Differential Diagnosis Weil's disease is not difficult to recognize in its full blown form The combination of sudden onset with fever leukocytosis jaundice muscle tenderness conjunctival suffusion and pleocytosis in the spinal fluid comprises a fairly characteristic syndrome Furthermore a history of contact with water likely to be contaminated by rats is helpful It is probable however that the diagnosis is overlooked in as many as one half the cases especially those of short duration and without jaundice The statement made previously that jaundice occurs in about 70 per cent of cases should be interpreted with this in mind Recognition of Weil's disease may be difficult in cases with predominant meningeal or renal manifestations In the early stages Weil's disease may simulate such acute infectious diseases as influenza trichinosis typhus fever brucellosis and the acute bacterial meningitides Diseases with which Weil's disease in its later manifestations may be confused include infectious hepatitis obstructive and hemolytic jaundice and acute glomerulonephritis If the various manifestations of Weil's disease are known and its possible existence is considered there is rarely much difficulty in making at least a presumptive diagnosis

Laboratory Diagnosis Experienced observers often are able to find leptospirae in dark field examination of the blood during the first 5 days of the disease Inexperienced observers however are likely to make an erroneous diagnosis of leptospiral infection because strands of fibrin being whipped about by Brownian motion are readily mistaken for leptospirae The organisms may be isolated from the blood by inoculation of guinea pigs mice or hamsters during the first few days of the disease Leptospirae can also be isolated from the urine between the second and fourth weeks of disease by animal inoculation in about 25 per cent of cases Good results have been obtained in a few laboratories by cultural isolation of leptospirae from the blood or urine Specific antibodies for leptospirae appear in the blood of patients with Weil's disease during the second week and often are present in extremely high titers agglutination with serum dilution of 1 10 000 is not uncommon and even 1 1 000 000 has been reported This test gives the best results when freshly prepared antigen is employed some workers prefer to use live leptospirae Efforts are being made to prepare stable soluble antigens which will be suitable for use in ordinary hospital laboratories obviating the necessity of maintaining cultures of all strains for diagnostic tests A presumptive diagnosis of Weil's disease can be made during the first few days of the disease on the basis of a muscle biopsy since the changes found in voluntary muscle are fairly characteristic The spinal fluid should always be examined when the possibility of Weil's disease is being considered the finding of xanthochromia and pleocytosis is strong evidence in support of the diagnosis Yellow discoloration of the spinal fluid does not occur in infectious hepatitis or other forms of jaundice unless the icterus is very marked and of long duration

Treatment In Europe good therapeutic effect has been reported following the use of high titer antiserum especially when given early in the disease Such serum is not available in the United States It has been suggested that blood or plasma from persons convalescent from Weil's disease might be of similar value

In experimental infections antibiotic therapy especially with penicillin and Aureomycin has proved effective in controlling leptospiral infection Furthermore case reports suggesting beneficial effect of these antibiotics in human disease have been published Generally however the clinical results have been disappointing In one well designed clinical test carried out during a small epidemic in Puerto Rico there did not appear to be any significant curative effect from any of several antibiotics alone and in combination Nevertheless one would probably be justified in giving the patient a trial of penicillin or Aureomycin in large doses e g 5 to 20 million units of penicillin or 3 to 4 Gm Aureomycin per day

The general care of the patient is the same as in any acute systemic infection It is unlikely that

are pathogenic for man and various animals They can be cultivated in the laboratory on media containing serum or other body fluids and can produce infection in such laboratory animals as guinea pigs hamsters mice and chick embryos Of some twenty serologically differentiated strains pathogenic for man the following have been shown to cause human infection in the United States *Leptospira icterohaemorrhagiae L canicola L pomona L grippotyphosa L autumnalis* Leptospirae are parasites of a number of wild and domestic animals some of which e g rats may excrete the spirochetes in the urine over long periods of time Human beings become contaminated when swimming in stagnant pools or canals or when engaged in such occupations as ditch digging sewer work fish cleaning poultry cleaning and farming Human infection has been acquired from mice swine and dogs as well as from rats The fact that leptospirae do not readily survive exposure to cold may account for the seasonal incidence of human leptospiral infection all forms being most frequent in the summer Cases of leptospiral infection are comparatively rare in children this may be due in part to some natural immunity but is doubtless related in large measure to the occupational factors in exposure The severest clinical form—Weil s disease—is usually observed in persons above the age of thirty whereas the milder forms such as aseptic meningitis and nonspecific grippelike illness are the usual expressions of leptospiral infection in adolescents and young adults

Pathogenesis The portal of entry in infections of human beings apparently is variable Evidence indicates that leptospirae can enter the body through the digestive and respiratory tracts or through abrasions of the skin In the earliest clinical stage of infection the organisms are present in the blood as a consequence of this dissemination they later cause inflammatory changes in many parts of the body including striated muscle liver kidney eye and meninges The lesions in *muscle* consist of focal necrosis attended by a variable degree of cellular reaction the majority of the cellular elements present consist of sarcolemma nuclei while inflammatory cells are comparatively rare The absence of vascular changes in this lesion differentiates it from similar muscle lesions which may occur in the rickettsial diseases Similar changes are encountered in the myocardium The *liver* is generally enlarged and icteric The histologic picture is that of slight focal degenerative phenomena in the liver cells with some evidence of liver cell regeneration and diffuse bile stasis in the bile canaliculi *Rare instances* of extensive central and midzonal necrosis are encountered The changes in the *kidney* consist of marked degeneration of the proximal convoluted tubules which contain large amounts of proteinaceous material There is generally a striking edema of the interstitial connective tissue with occasional small foci of chronic inflammatory cell infiltration Inflammation of the *meninges* is usually of low grade intensity with a *predominantly mononuclear* pleocytosis in the spinal fluid In those cases which terminate fatally there is deep jaundice of all tissues and widespread petechial hemorrhages are encountered Leptospirae are best demonstrated in sections of kidney and liver

WEIL S DISEASE

Definition Weil s disease is an acute febrile illness characterized by fever leukocytosis muscle pains and signs of acute hepatitis and nephritis

Manifestations After an incubation period of 8 to 12 days the illness usually begins suddenly often with a chill followed by a remittent *fever* ranging between 102 and 104 F *Soon after the onset* the patient begins to suffer from *muscle pains* which are most marked in the lumbar region and in the calves of the legs Headache anorexia and nausea may be experienced *during this period* There may also be soreness of the throat and cough *Fever* usually persists for 4 to 6 days terminating by rapid lysis *Jaundice* occurs in about 70 per cent of cases usually *appearing between the third and* sixth days At this time the liver is somewhat enlarged and moderately tender Jaundice usually increases in intensity for 2 to 4 days after its appearance then subsides gradually over a period of 7 to 10 days except in those cases which terminate fatally in which the severity of jaundice may increase steadily until death Splenomegaly is not common The urine output often diminishes during the latter part of the first week and in those patients who suffer severe renal involvement there may be almost complete suppression of urine in fatal cases this is usually an important factor If recovery is to occur the urine output will gradually return to normal during the second week Marked *suffusion of the conjunctiva* is likely to be present and is a finding of some help in diagnosis particularly when the underlying sclera is icteric *Cutaneous hemorrhages* of varying size may occur in the severest cases but they are not common Scarlatiniform and morbilliform *rashes* have been described but they also are uncommon *Iridocyclitis* manifested by photophobia and circumcorneal congestion occurs in 5 to 10 per cent of patients *Signs of meningeal irritation* severe headache and stiffness of the neck may be observed at any time during the first week of the disease

Recovery is gradual Most patients are asymptomatic by the end of the second week except for a rather marked asth[illegible]

nephritis The onset is usually sudden often with chill Temperature rises to 102 to 105 F and remittent fever continues for 3 or 4 days then subsides There may be a second brief febrile episode after a free period of 1 to 3 days The chief symptoms are headache and muscle pains occasionally there is acute arthritis so that the picture simulates acute rheumatic fever Conjunctival suffusion and muscle tenderness are the chief physical findings The spleen is seldom palpably enlarged In 10 per cent of cases there is a fleeting maculopapular exanthem involving the trunk or thighs Gastrointestinal and respiratory symptoms are not prominent There is usually a moderate elevation of the leukocyte count Diagnosis can be made by demonstration of leptospiremia or by serologic tests as previously described These illnesses usually are self limited and complete recovery is to be expected

Iridocyclitis

Iridocyclitis may occur as a complication of systemic leptospiral infection either during or immediately following the other manifestations In some instances it comes on abruptly months after the other illness Under such circumstances the relationship of the ophthalmic lesion to the preceding illness may not be appreciated The course is usually benign and complete or nearly complete return of ocular function can be anticipated after 2 to 4 weeks

Acute Nephritis

Cases of leptospiral infection due to *L icterohaemorrhagiae* have been reported in which manifestations of nephritis were the outstanding feature The illnesses have had sudden onset with chills and high fever—higher than would be expected in cases of acute glomerulonephritis There have been oliguria hematuria cylindruria and azotemia Recovery has begun about the end of the second week with restoration of normal kidney function by the end of the fourth week

157 RELAPSING FEVER

Paul B Beeson

Definition Relapsing fever is an acute infectious disease caused by spirochetes belonging to the genus *Borrelia* The outstanding clinical characteristic is a relapsing type of fever

Etiology Members of the genus *Borrelia* are slender flexible spirochetes 10 to 20 μ in length (Fig 142) They move with a corkscrewlike action *Borrelia* species are pathogenic for many rodents including rats mice and squirrels They can be cultured in media enriched with serum or blood The strain encountered most commonly in North America is *Borrelia recurrentis* In other areas *Borrelia novyi* and *Borrelia duttonii* are of clinical importance

Epidemiology and Pathogenesis Relapsing fever occurs in many parts of the world including Asia Africa Europe and South and North America Wild rodents appear to be the natural reservoirs of the infection The disease is transmitted to man by insect vectors In some parts of the world human beings are infected by the bite of ticks (*Ornithodoros*) while in other localities as in Asia the

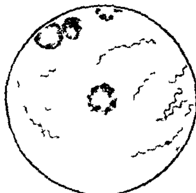

FIG 142 *Borrelia recurrentis* from blood of a man with relapsing fever (Kolle and Wassermann) (*Stitt Clough and Branham Practical Bacteriology Hematology and Parasitology* New York The Blakiston Division McGraw Hill Book Company Inc)

diet will have much influence on the course of the hepatitis Patients with oliguria should not be waterlogged with too much parenteral fluid and salt however

Prognosis The reported fatality rates refer only to the more severe cases of leptospiral infection In such cases presenting evidence of hepatitis and nephritis the fatality rate is in the range of 5 to 10 per cent

PRETIBIAL FEVER

The disease was first described by Bowdoin who studied an outbreak of 35 cases at Wrens Ga in 1940 Daniels and Grennan described a similar disease among soldiers stationed at Fort Bragg N C in 1942 It recurred at Fort Bragg in 1943 and 1944 In 1944 Tatlock isolated the etiologic agent by inoculating guinea pigs with blood from a patient First thought to be a filtrable virus this agent was later shown by Gochenour et al to be *L autumnalis* a leptospira previously known to cause human disease in Japan

Little is known regarding the pathogenesis of pretibial fever It is interesting to note that all the cases from Fort Bragg occurred in a localized segment of the reservation which was located near a small stream In addition all patients from the outbreak in Georgia had gone swimming in Brushy Creek (hence the original name of the disease *Brushy Creek fever*) The significance of these observations is not clear at present

The incubation period appears to be 10 to 15 days or longer The onset is usually sudden with frontal headache muscle pains backache post orbital pain chills or chilliness and fever About one third of the patients have a transitory sore throat and cough There may be nausea vomiting and bradycardia The fever is spiking in nature with recurrent chills It ranges between 100 and 105 F and persists for 4 to 8 days An unusual eruption appears on about the fourth day of illness in most of the patients The lesions consist of erythematous blotches with irregular margins which are raised warm and slightly tender to touch The rash characteristically involves the pretibial regions but occasionally is diffusely distributed over the entire body The eruption usually persists for only 24 to 48 hr The spleen is almost always palpable early in the disease but there is no generalized lymphadenopathy

A mild leukopenia is a feature of the disease usually appearing between the third and fifth days of illness The differential count shows no significant change The spinal fluid in three patients with stiff ness of the neck was normal

Full recovery takes place rapidly after subsidence of the fever

BENIGN ASEPTIC MENINGITIS

In young individuals leptospiral infection may take the form of an acute systemic disease dominated by signs of meningeal inflammation and without evidence of involvement of the liver or kidneys Several strains have been shown to be capable of eliciting this clinical syndrome including *L pomona L icterohaemorrhagiae L canicola* and *L sejro*

The manifestations are hardly distinguishable from those of the acute viral meningitides such as lymphocytic choriomeningitis nonparalytic polio myelitis and mumps The onset is acute with chilliness or chills malaise muscle pain headache photophobia and pain on movement of the eyeballs Fever is variable from 100 to 104 F After a day or two headache becomes more intense and there are pain and stiffness in the neck and back Examination at this time may reveal some generalized muscle tenderness and conjunctival suffusion (occasionally subconjunctival hemorrhages) together with signs of meningitis Routine laboratory tests show normal urine and blood without the leukocytosis so regularly seen in Weil s disease The spinal fluid is under slightly increased pressure its protein content is elevated to 50 to 100 mg per 100 ml its dextrose content is normal and there is a pleocytosis The cells are predominantly mononuclear rarely as many as 50 per cent may be polymorphonuclear leukocytes The total count is usually between 50 and 300 per cubic millimeter this point may be of some help in differentiation from mumps meningitis and lymphocytic choriomeningitis where the total count is often higher

The disease is self limited fever and other symptoms subside in 6 to 12 days There are no residual effects In view of the short benign course and lack of convincing evidence of benefit from antibiotic therapy the only treatment indicated is that for relief of symptoms Specific diagnosis may be achieved by the methods described in connection with Weil s disease

THE "NONSPECIFIC LEPTOSPIRAL ILLNESSES

In some parts of the world mild leptospiral illnesses are recognized fairly commonly They are usually acquired through some occupational exposure hence are designated by such names as cane field fever swamp fever" water fever" dairy grippe rice field fever etc The leptospirae associated include *L icterohaemorrhagiae L canicola L pomona L grippotyphosa L sejro L mitis* and *L bataviae*

The clinical pattern in this form of leptospiral infection has been likened to a mild form of Weil s disease with little or no evidence of hepatitis or

of the world It is recommended that two injections of this drug be given intravenously 3 to 5 days apart the dose being 0 04 Gm for adults Arsenical therapy is likely to cause a Herxheimer like reaction 4 to 12 hr after the injection evidenced by rise in temperature malaise and intensification of symptoms This reaction can cause death of the patient when superimposed at the height of a severe febrile attack Consequently it is usually recommended that specific therapy be withheld in severely ill patients until a natural crisis occurs The patient should be given supportive therapy meanwhile in the form of parenteral fluids and electrolytes Mapharsen is then administered at the onset of the next febrile period or a day or two before it is expected Further treatment is indicated in the event of a relapse

Prognosis Relapsing fever is not in itself a highly fatal infectious disease However because it occurs frequently under conditions of famine and extreme poverty and therefore may be associated with other infections and malnutrition a significant fatality rate is usually ascribed to it Reported fatality rates have varied from 2 to 50 per cent they would probably be less than 2 per cent among otherwise healthy persons given proper treatment

158 RAT BITE FEVER—*SPIRILLUM MINUS* INFECTION

Paul B Beeson

Definition Rat bite fever is an acute infectious disease caused by *Spirillum minus* and characterized by relapsing fever arthritis and a skin eruption

Etiology The causative organism is a spirillum 2 to 5 μ in length it has two to five broad spirals and is propelled by flagella The organism is easily identified in dark field preparations by its quick darting motility It is found occasionally in the blood of apparently healthy rats mice and guinea pigs

Epidemiology In man infection by *S minus* is almost always acquired through the bite of a rat It is commonest in infants and young children but may also occur in adults Rats may attack sleeping persons and will bite anyone attempting to catch or handle them

Manifestations The incubation period varies widely from 1 to 6 weeks With the onset of symptoms the site of the rat bite usually becomes swollen tender and purplish red The regional lymph nodes also become enlarged There is fever usually relapsing A chill may occur at the onset of a febrile period Bouts of fever last 2 to 4 days and are separated by afebrile periods also lasting 2 to 4 days The principal symptoms during febrile episodes are malaise headache sweating photophobia nausea and vomiting In perhaps 50 per cent of cases there is *arthritis* with redness and swelling of one or more large joints In a similar proportion of cases a *skin eruption* occurs usually on the extremities The rash is frequently asymmetric in its distribution and most commonly consists of reddish or purplish plaques which may become large and confluent The disease tends to run a prolonged course usually 4 to 8 weeks but cases have been reported in which clinical manifestations continued for more than a year One case of subacute bacterial endocarditis due to this organism has been observed

Laboratory Findings The total leukocyte count may be normal or there may be a moderate leukocytosis In prolonged cases there is a normochromic anemia Biologic false positive serologic tests for syphilis are frequent The *S minus* seldom can be found in the blood or tissues of patients suffering from this infection and can usually be demonstrated only by transmission to laboratory animals Mice or guinea pigs may be inoculated intraperitoneally with the patient s blood The *S minus* usually can be found in the blood of the animal by dark field examination 1 to 3 weeks later Since laboratory animals may be naturally infected with *S minus* precautions must be taken to ensure that the animals used in this test are free of infection before inoculation

There are reports of isolation of this *Spirillum* from the blood by culture using routine bacteriologic blood culture technique

Differential Diagnosis It is important to inquire about rat bite in all patients with a relapsing type of fever In patients with a history of rat bite the principal problem is in differentiating between *S minus* infection and *Streptobacillus moniliformis* This cannot be done with certainty on clinical grounds but a prolonged incubation period and

principal vector is the body louse The excreta of the louse may be infectious and disease in man may follow the crushing of a louse on the skin especially when the area is scratched Fleas and bedbugs also have been suspected of transmitting relapsing fever It is likely then that under certain circumstances an animal reservoir is not necessary for perpetuation and instead that infection is transmitted from man to vector to man In the United States relapsing fever has been recognized predominantly in the West and in Texas in these areas ticks appear to be the principal vectors with wild rodents or bats as reservoirs

After inoculation into man by contact with the excreta or by the bite of an arthropod *Borrelia* is apparently disseminated by way of the blood stream and lymphatics The large number of spirochetes present in the blood of an infected person suggests that these organisms are capable of growing in the blood itself They have also been demonstrated in the cerebrospinal fluid during the acute stage of relapsing fever Autopsy in fatal cases discloses their presence in the brain spleen kidneys and liver

Manifestations It is often impossible to determine the *incubation period* in individual cases but there is epidemiologic evidence to suggest that 5 to 11 days is the usual time *Symptoms* develop abruptly with chilliness fever headache muscle aching and nonproductive cough Nausea and vomiting are common symptoms Some patients complain of paresthesias of the face and tongue The patient appears acutely ill with flushed face and injected conjunctival and pharyngeal mucous membranes At the height of the fever there may be dizziness mental cloudiness or delirium Signs of extracellular fluid deficit—dry inelastic skin and wrinkled tongue—are often present *Tenderness of the calf muscles* is a characteristic physical finding *Jaundice* occurs in a small proportion of cases usually after several days of fever A transitory erythematous rash may be observed especially about the neck and shoulders In severe cases there may be *petechiae* *Enlargement of the spleen* is observed in about half of all cases The pattern of the temperature curve is somewhat variable Usually there is an elevation to 103 to 105 F The fever may be sustained or remittent

Course of Disease The febrile bout usually persists from 4 to 15 days and then subsides spontaneously At the termination of fever there is usually profuse sweating and the temperature may fall to 96 or 97 F gradually returning to normal during the succeeding day or two A relapse is to be expected several days later with a repetition of the same series of events Unless specific therapy is administered it is usual for a patient to have three to five attacks of fever after which the disease ceases spontaneously Additional relapses may occur but the usual end result is complete cure of the infection Death from relapsing fever is usually associated with hyperpyrexia a hemorrhagic tendency and circulatory failure

Complications are not numerous Nosebleed and gastrointestinal bleeding occur in severe cases Pneumonia may be observed at the time of death Orchitis and iridocyclitis are rare complications In China an unusual frequency of *Salmonella enteritidis* septicemia has been observed in patients with relapsing fever

Laboratory Findings The leukocyte count is variable but most commonly is between 10 000 and 15 000 per cubic millimeter The spinal fluid may show increased protein content and a pleocytosis predominantly mononuclear

A *specific diagnosis* nearly always can be made during febrile periods and occasionally even during remissions by the finding of *Borrelia* in stained smears of the peripheral blood Giemsa or Wright s stain is satisfactory If the organisms cannot be found by this method mice should be inoculated intraperitoneally with the patient s blood *Borrelia* can then be found in the blood of these animals from 16 hr to 3 days later if the patient is suffering from relapsing fever

Because of the ease with which a specific diagnosis can be made from the blood smear serologic diagnostic tests are not needed It is worth noting however that false positive serologic tests for syphilis are obtained in about 10 per cent of patients with relapsing fever and that nearly all patients develop agglutinins for *Proteus* OX K

Differential Diagnosis This disease has to be differentiated from other acute infectious diseases particularly those which may be associated with a relapsing type of fever such as malaria meningococcemia and rat bite fever At the onset of the disease the picture simulates that of Weil s disease Under conditions of poverty and famine the problem of diagnosis may be increased by concurrent epidemics of typhus fever malaria and tuberculosis Fortunately a specific diagnosis of relapsing fever usually can be made simply by microscopic examination of a stained smear of blood

Treatment Initial experience with penicillin therapy was not encouraging but that may be attributed to the fact that the dosages employed were small by present standards Excellent results have been reported in small series of cases when 800 000 or more units were given per day Chlortetracycline is perhaps even more effective and appears now to be the agent of choice Dosage recommended is 2 Gm daily for 7 to 10 days

Therapy with arsenical preparations such as Mapharsen (arsenoxide) is regarded as highly effective in relapsing fever observed in some parts

of the world It is recommended that two injections of this drug be given intravenously 3 to 5 days apart the dose being 0 04 Gm for adults Arsenical therapy is likely to cause a Herxheimer like reaction 4 to 12 hr after the injection evidenced by rise in temperature malaise and intensification of symptoms This reaction can cause death of the patient when superimposed at the height of a severe febrile attack Consequently it is usually recommended that specific therapy be withheld in severely ill patients until a natural crisis occurs The patient should be given supportive therapy meanwhile in the form of parenteral fluids and electrolytes Mapharsen is then administered at the onset of the next febrile period or a day or two before it is expected Further treatment is indicated in the event of a relapse

Prognosis Relapsing fever is not in itself a highly fatal infectious disease However because it occurs frequently under conditions of famine and extreme poverty and therefore may be associated with other infections and malnutrition a significant fatality rate is usually ascribed to it Reported fatality rates have varied from 2 to 50 per cent they would probably be less than 2 per cent among otherwise healthy persons given proper treatment

158 RAT BITE FEVER—*SPIRILLUM MINUS* INFECTION

Paul B Beeson

Definition Rat bite fever is an acute infectious disease caused by *Spirillum minus* and characterized by relapsing fever arthritis and a skin eruption

Etiology The causative organism is a spirillum 2 to 5 μ in length it has two to five broad spirals and is propelled by flagella The organism is easily identified in dark field preparations by its quick darting motility It is found occasionally in the blood of apparently healthy rats mice and guinea pigs

Epidemiology In man infection by *S minus* is almost always acquired through the bite of a rat It is commonest in infants and young children but may also occur in adults Rats may attack sleeping persons and will bite anyone attempting to catch or handle them

Manifestations The incubation period varies widely from 1 to 6 weeks With the onset of symptoms the site of the rat bite usually becomes swollen tender and purplish red The regional lymph nodes also become enlarged There is fever usually relapsing A chill may occur at the onset of a febrile period Bouts of fever last 2 to 4 days and are separated by afebrile periods also lasting 2 to 4 days The principal symptoms during febrile episodes are malaise headache sweating photophobia nausea and vomiting In perhaps 50 per cent of cases there is *arthritis* with redness and swelling of one or more large joints In a similar proportion of cases a *skin eruption* occurs usually on the extremities The rash is frequently asymmetric in its distribution and most commonly consists of reddish or purplish plaques which may become large and confluent The disease tends to run a prolonged course usually 4 to 8 weeks but cases have been reported in which clinical manifestations continued for more than a year One case of subacute bacterial endocarditis due to this organism has been observed

Laboratory Findings The total leukocyte count may be normal or there may be a moderate leukocytosis In prolonged cases there is a normochromic anemia Biologic false positive serologic tests for syphilis are frequent The *S minus* seldom can be found in the blood or tissues of patients suffering from this infection and can usually be demonstrated only by transmission to laboratory animals Mice or guinea pigs may be inoculated intraperitoneally with the patient s blood The *S minus* usually can be found in the blood of the animal by dark field examination 1 to 3 weeks later Since laboratory animals may be naturally infected with *S minus* precautions must be taken to ensure that the animals used in this test are free of infection before inoculation

There are reports of isolation of this *Spirillum* from the blood by culture using routine bacteriologic blood culture technique

Differential Diagnosis It is important to inquire about rat bite in all patients with a relapsing type of fever In patients with a history of rat bite the principal problem is in differentiating between *S minus* infection and *Streptobacillus moniliformis* This cannot be done with certainty on clinical grounds but a prolonged incubation period and

few or no manifestations of arthritis suggest a diagnosis of *S minus* infection Laboratory tests should be made for both organisms The significance of a previous rat bite may not be appreciated in cases with a long incubation period and the disease may be confused with other infections characterized by relapsing fever such as malaria, meningococcemia *Borrelia recurrentis* infection and occasionally pyogenic infection

Treatment This infection usually responds promptly to treatment with arsenical preparations such as arsenoxide (Mapharsen) or neoarsphenamine Doses appropriate to the patient s age and size and equivalent to those used in the treatment of syphilis are satisfactory The usual practice is to give two or three injections at 3 or 4 day intervals The effect of penicillin in this infection has not been determined adequately in man but the results of animal experiments are encouraging and clinical trial is warranted There are also a few reports of prompt clinical response to treatment with streptomycin and oxytetracycline

Prognosis In the absence of serious complicating illnesses rat bite fever caused by *S minus* is never fatal

Section 12 Rickettsial Infections

159 INTRODUCTION AND PATHOLOGY

T E Woodward and J E Smadel

The rickettsial diseases of man consist of a variety of clinical entities caused by microorganisms of the family Rickettsiaceae The rickettsiae are obligate intracellular parasites about the size of bacteria and are usually seen microscopically as pleomorphic coccobacillary organisms Each of the rickettsiae pathogenic for man is capable of multiplying in one or more species of arthropod as well as in animals and man Indeed the majority of the rickettsiae are maintained in nature by a cycle which involves an insect vector and an animal reservoir and infection of man is unimportant in the cycle Q fever is a partial exception to this generalization since man usually contracts the infection via the respiratory route by inhaling rickettsiae as an aerosol derived from infected animal or tick excretions however this rickettsiosis is also maintained in nature in ticks and their animal hosts Epidemic typhus presents a number of points of dissimilarity to most of the other rickettsioses since the natural cycle of infection involves only man and the louse Moreover the agent of epidemic typhus unlike the other rickettsiae has not established a well-organized parasitic relationship which ensures its perpetuation either in its mammalian host and reservoir (man) or in its arthropod host (louse) Man frequently dies from epidemic typhus and only rarely do recovered patients serve as a suitable reservoir (i e suffer a recurrence in later years resulting in what is known as Brill s disease) and infect their body lice Furthermore the louse is relatively poorly adapted to perpetuation of the rickettsiae which induce a fatal disease in this arthropod In contrast most rickettsiae cause only a mild disease in their mammalian hosts and do not affect their arthropod host adversely indeed a number are transmitted transovarially in insects from one generation to another

The rickettsial infections of man encountered in the United States are in order of their frequency murine typhus Rocky Mountain spotted fever rickettsialpox Q fever and Brill s disease (recurrent epidemic typhus) These diseases will receive particular emphasis however students and practitioners of medicine in this generation must be familiar with infections which they may encounter in other parts of the world or which might reappear in the United States therefore some space will be devoted to epidemic typhus scrub typhus and certain of the foreign diseases of the spotted fever group

A compendium of information on the rickettsial diseases is presented in Table 93 Since each of the rickettsioses encountered in America responds therapeutically to the broad spectrum antibiotics

the table contains no mention of therapy Procedures for diagnostic isolation of the rickettsiae are omitted from the table because they generally are less useful than serologic methods and the techniques which they require are highly specialized and hazardous for laboratory personnel Information on isolation procedures may be found in text books devoted to viral and rickettsial diseases

History of the Rickettsial Diseases Of all the afflictions of mankind the rickettsial diseases particularly epidemic typhus rank among the foremost as a cause of human suffering and death Classical typhus fever undoubtedly existed during ancient times although Zinsser cites an outbreak of illness in 1013 in a monastery near Salerno Italy as the first probable recorded incidence of this disease Typhus fever through its able transmitter the body louse has always identified itself intimately with wars famines and human catastrophes of all kinds Alone it has cast a decisive vote in the outcome of many military campaigns

The record of deaths from epidemic typhus in this century in the Balkan countries and in Poland and Russia reaches astounding figures Serbia in 1915 suffered an epidemic of major proportions with 150 000 dead and a mortality rate ranging from 20 to 60 per cent Typhus ravaged Russia and eastern Poland from 1915 to 1922 infecting 30 million of the inhabitants and causing deaths estimated at 3 million

The past two decades have seen the development of amazingly satisfactory methods for the prevention and treatment of the rickettsioses of man In fact these measures have been so successful that the rickettsioses have become of minor importance in the United States and in a number of other countries Although conquered the rickettsioses have not been eliminated and they could again become rampant if the will to control them the present high standards of sanitation and the necessary industrial capacities for production of insecticides and therapeutic agents should be decreased

through war or disaster It is worthwhile to review the classical milestones representing the clinical and scientific contributions which have resulted in the understanding and conquest of the rickettsial infections

Gerhard in 1836 differentiated typhoid fever from louse borne typhus fever In 1899 Maxcy described the clinical manifestations of Rocky Mountain spotted fever In a series of studies from 1906 to 1909 Ricketts for whom the rickettsiae microorganisms are named successfully transmitted the disease to guinea pigs incriminated the wood tick as a vector and observed rickettsiae in smears prepared from the blood of man and in the tick tissues

Nicolle in 1909 reproduced typhus fever in monkeys and demonstrated transmission by the body louse Von Prowazek in 1914 and Da Rocha Lima in 1916 demonstrated small microorganisms in the tissues of lice taken from typhus patients

Brill in 1910 recognized a febrile disease in patients in New York City as examples of mild epidemic typhus unassociated with lousiness Zinsser in later years (1934) postulated that Brill s disease was a recurrent form of typhus occurring in patients during periods of stress or waning immunity Subsequent studies have essentially confirmed Zinsser s hypothesis

Weil and Felix working with typhus patients in Poland in 1915 recognized that agglutinins for certain proteus organisms appeared in the serum of convalescent patients The Weil Felix reaction although nonspecific in character affords a simple and valuable screening method for the diagnosis of certain rickettsioses

In 1926 Maxcy on purely epidemiological evidence surmised that typhus in this country had its reservoir in rodents and was transmitted to man by ticks or fleas Confirmation of Maxcy s hypothesis was obtained in Baltimore in 1930 by Dyer and others when they isolated rickettsiae from the brains of rats and shortly thereafter incriminated the flea as a vector This disease caused by *Rickettsia mooseri* and now designated endemic or murine typhus is distinct from epidemic typhus or Brill s disease

The development of suitable vaccines and specific diagnostic antigens was impeded until it was possible to prepare appreciable quantities of highly infectious rickettsial material in the laboratory The most important steps were (1) the Weigl vaccine (1930) which was a phenolized suspension of gut tissue obtained from body lice which had been injected intrarectally with the rickettsiae of epidemic typhus (2) the killed murine typhus vaccine prepared by Castaneda (1939) from lung tissues of rats injected intranasally and (3) the inactivated Rocky Mountain spotted fever vaccine obtained by Cox (1941) from infected yolk sacs of embryonated hen s eggs Each of the developments was applied in principle to other rickettsial agents but the low cost and relative simplicity of the egg techniques have led to their general use for preparation of vaccines and diagnostic antigens The specific diagnostic complement fixation tests for the rickettsial diseases now used in the United States stem directly from the pioneering work of Bengtson in Q fever and of Plotz on the spotted and typhus fevers during the early 1940s

The years of the Second World War saw many strides in the conquest of the rickettsioses perhaps greatest among these were the highly successful attacks on the insect vectors of disease The louse cide DDT proved to be ideal for control by dusting on the clothes of infested persons The epidemic at Naples during the winter of 1943 to 1944 established a milestone since it was the first to be suppressed within several weeks mainly by the use of insecticides On the other side of the world scrub typhus (mite borne typhus) was creating a major problem in military medicine in the Pacific area Here too the major contributions to successful control were concerned with application of miticidal chemicals to the person and his clothes

Specific therapy of rickettsial infections is a rather recent development Although hyperimmune rabbit serum (Topping 1939) ameliorated the course of Rocky Mountain spotted fever if given during the early stages and paraaminobenzoic acid (Yeomans 1944) was found to be effective in typhus fever the advent of broad spectrum antibiotics first chloramphenicol then Aureomycin in 1948 and later Terramycin provided the dramatic therapeutic results in each of the rickettsioses

Table 93 lists several rickettsial diseases which have not been mentioned in this historical review While important in themselves except for Q fever these have not been the subject of work which contributed broad principles applicable to the group

Pathogenesis Rickettsial diseases of man result from infection by one of two routes i e the skin or the respiratory tract Agents of the typhus and spotted fever group of rickettsiae are introduced into the skin through the bite of the infected arthropod vector Ticks and mites which transmit the spotted fevers and scrub typhus inoculate the rickettsiae directly into the dermis during feeding The louse and flea which transmit epidemic and murine typhus respectively deposit infected feces on the skin infection occurs when organisms are rubbed into the puncture wound made by the arthropod a process facilitated by scratching the itching bitten area The rickettsia of Q fever gains entry through the respiratory tract by inhalation of infected dust moreover i route

may occasionally be indicted in epidemic typhus when infection results from inhalation of dried infected louse feces

While multiplication of organisms probably takes place at the original site of entry in all instances local lesions appear with considerable regularity only in certain diseases viz the initial cutaneous lesions of scrub typhus rickettsialpox and African tick typhus and the pneumonitis which develops in about half the persons infected with Q fever Investigations have demonstrated that volunteers infected with either scrub typhus or Q fever develop rickettsemia late in the incubation period often some hours before the onset of fever Similar events probably occur in all the rickettsial diseases certainly circulating rickettsiae can be detected during the early febrile period in practically all patients Little is known about the pathogenesis of infection during the midportion of the incubation period However it is reasonable to assume that during this time in patients with typhus or spotted fever a transient low grade rickettsemia results from release of organisms multiplying at the initial site of infection and that this seeds infection in the endothelial cells of the vascular tree Vascular lesions developing at such sites could account for the pathologic changes including the rash (see following section on Pathology)

The underlying cause of the toxic febrile state which characterizes the rickettsial diseases as well as most infectious diseases remains unknown If the products of destruction of infected cells contribute to the state then fairly extensive damage is required i e more than that occurring late in the incubation period of scrub typhus when enough infected cells are destroyed to liberate appreciable numbers of rickettsiae into the circulation yet the patient remains afebrile and feels well Several rickettsial species contain type specific toxins which are lethal for mice what role these play in the toxic febrile state of patients remains unknown Cortisone suppresses the febrile response in patients but does not prevent death of mice injected with rickettsial toxins

Pathology The basic pathologic lesions in the spotted and typhus fever groups of diseases are in the small vessels The most diverse and extensive of these are found in Rocky Mountain spotted fever Here swelling proliferation and degeneration of the endothelial cells occur frequently with thrombus formation which partially or completely obliterates the lumen The muscle cells of the arteriole undergo degeneration represented by swelling and fibrinoid changes The adventitial tissues are infiltrated with mononuclear leukocytes lymphocytes and plasma cells Plate II illustrates the typical lesions found in a small vessel of the skin of a patient with spotted fever Such vascular damage is scattered in localized regions along the arteries veins and capillaries with normal architecture prevailing throughout most of the vascular bed The changes in murine epidemic and scrub typhus fevers resemble those in Rocky Mountain spotted fever as regards the endothelial swelling and the adventitial inflammatory infiltrations however thrombosis is uncommon and involvement of the musculature is rare

The vascular changes with resultant lesions in adjacent parenchymatous tissues occur throughout the vital organs but are most conspicuous in the heart lung and brain Interstitial myocarditis occurs in each member of this group of diseases but is usually most extensive in Rocky Mountain spotted fever and in scrub typhus In the brain the glial nodule is found in all members of the group but microinfarcts in the brain tissue or in the myocardium are most often observed in spotted fever The glial nodule represents a cellular response in an area adjacent to a small vascular lesion The microinfarct on the other hand constitutes anemic necrosis in an area whose supplying vessel has been occluded by the intimal reaction or thrombosis Visceral lesions in most of the other organs are similarly dependent upon the primary vascular abnormalities or are those nonspecific changes associated with severe febrile illnesses

A rickettsial pneumonitis occurs at least to some extent in many patients with spotted or typhus fever and is the characteristic pathologic change in patients with Q fever This is an interstitial pneumonitis which closely resembles that encountered in primary atypical pneumonia and viral influenzal pneumonia The process is patchy and consists macroscopically of areas of congestion and edema with gray granular consolidation Microscopically in the consolidated areas the alveoli are filled with compact fibrinocellular exudate containing lymphocytes plasma cells large mononuclear cells and erythrocytes but few if any polymorphonuclear leukocytes The alveolar epithelium is hyperplastic and the intraalveolar septa as well as the peribronchial and perivascular tissues are thickened by accumulations of leukocytes such as are found within the alveolar lumena

Rickettsiae can occasionally be observed microscopically in sections of tissue from persons dying from rickettsial diseases However special fixation of tissues special staining techniques infinite patience for work with the oil immersion objective and luck are required for success The failure to demonstrate rickettsiae in histologic section is of no diagnostic significance

Laboratory Diagnosis Diagnostic procedures which depend on isolation of the etiologic agent from blood or other clinical material are expensive time consuming and hazardous to laboratory per

Table 94 SEROLOGIC DIAGNOSIS OF RICKETTSIAL DISEASES IN THE UNITED STATES

Group	Disease	Weil Felix reaction				Complement fixation tests with type-specific antigen

sonnel Except in unusual circumstances the currently available serologic tests are adequate for laboratory confirmation of the clinical diagnosis in each of the rickettsial diseases

As in most serologic diagnostic procedures the demonstration of a rise in titer of specific antibody during convalescence is of prime importance in establishing the laboratory confirmation Table 94 summarizes the serologic results usually encountered in persons who suffer from rickettsial diseases in the United States The Weil Felix test employing *Proteus* strains OX 19 and OX 2 gives positive results in patients with spotted fever and murine typhus and negative results in those with rickettsial pox and Q fever It is useful as a screening procedure but cannot be relied upon to differentiate spotted fever from murine typhus

Complement fixation tests employing group specific rickettsial antigens provide data which clearly differentiate the most common infections i e murine typhus Rocky Mountain spotted fever and Q fever Moreover if type specific rickettsial antigens are employed it is generally possible to distinguish rickettsialpox from spotted fever and Brill's disease from murine typhus

Specific antibiotic therapy has little effect on the time of appearance of antibodies or on their ultimate titer provided treatment is begun some days after onset of the rickettsial disease However if the illness is cut short by early and vigorous treatment then antibody production may be delayed for a week or so and also the maximal titers attained may be below those illustrated in Table 94 Under these circumstances a sample of blood taken 4 to 6 weeks after onset of illness should be examined

Except for normochromic anemia which occurs in patients severely ill with rickettsial diseases there are no other distinctive alterations of the hematologic picture The white blood cell count in Rocky Mountain spotted fever rickettsialpox murine and epidemic typhus Brill's disease Q fever and others is usually within the normal range 6 000 to 10 000 per cubic millimeter Leukopenia is occasionally observed and in the presence of complications such as superimposed infections and extensive vascular lesions moderate leukocytosis occurs The differential blood count is usually normal

160 ROCKY MOUNTAIN SPOTTED FEVER

T E Woodward and J E Smadel

Definition Rocky Mountain spotted fever an acute febrile illness caused by *Rickettsia rickettsii* is transmitted to man by ticks The disease is characterized by sudden onset with headache and chills and by fever which persists for 2 to 3 weeks A characteristic exanthem appears on the extremities and trunk about the fourth day of disease this rash like other anatomical manifestations of the disease stems from focal areas of endangiitis scattered throughout the body Delirium shock and renal failure occur in the severely ill Agglutinins for the proteus organisms and specific complement fixing antibodies appear in the patient's serum during the second or third week of disease The broad spectrum antibiotics are highly specific therapeutically A review of the pertinent historical features is given in Chap 159

Etiology and Epidemiology The causative microbe *Rickettsia rickettsii* represents the prototype for the rickettsial group of agents The minute organisms about 1 μ in length and 0 2 to 0 3 μ in width are purple when stained by Giemsa's method or red by Macchiavello's technique and often occur in pairs surrounded by a halo as if encapsulated (see Plate II) The rickettsiae grow in the nucleus as well as in the cytoplasm of infected cells of ticks mammals and embryonated eggs the intranuclear situation of the organisms is shared by the other members of the spotted fever goup but not by rickettsiae of the typhus group *Rickettsia rickettsii* are readily distinguishable from the agents of the typhus fevers by cross immunity tests in guinea pigs and by complement fixation tests employing antigens prepared from infected yolk sac tissues The differentiation of *R rickettsii* from closely related members of the spotted fever group frequently requires elaborate procedures Strains of the agent of Rocky Mountain spotted fever vary considerably in their virulence for man and animals

The first reports of spotted fever in Idaho and Montana during the final decade of the last century led to the name Rocky Mountain spotted fever However the disease is now known to occur in all states except Maine and Vermont as well as in Canada Mexico Colombia and Brazil Although related diseases are found on other continents this particular infection is limited to the Western Hemisphere About five hundred cases of spotted fever occur annually in the United States the mortality in the days before specific therapy was about 20 per cent The attack rate per unit of population is highest in Wyoming but the rates in Delaware Maryland Virginia and North Carolina are about the same as those in Montana Idaho Nevada and Utah Moreover approximately two fifths of all cases in the United States occur each year in the Middle Atlantic states just mentioned

A number of species of ticks are found infected with *R rickettsii* in nature but only two species are important in transmitting spotted fever to man These are *Dermacentor andersoni* the wood tick which is the principal vector in the West and *D variabilis* the dog tick which assumes this role in the East Ricketts almost half a century ago demonstrated that infected adult female ticks transmit the agent transovarially to at least some of their offspring Ticks which become infected either through the egg or at one of the stages during their developmental cycle by feeding on an infected mammal harbor the rickettsiae throughout their lifetime which may be as long as several years Thus the tick probably serves as a reservoir in addition to being a vector Small wild mammals are suspected of playing an important role in spreading the rickettsiae in nature by infecting those new

ticks which feed on them during that period of the disease when rickettsemia is occurring

Disease in man is generally acquired from the bite of an infected tick However transmission is unlikely unless the tick remains attached for a number of hours Infection may also be acquired through abrasions in the skin which become contaminated with infected tick feces or tissue juices hence the hazard associated with crushing ticks between the fingers when removing them from persons or animals

There are seasonal variations in the incidence of cases of spotted fever as well as differences in age and sex distribution of cases In each instance these differences are related to exposure to ticks Thus most patients are seen during the period of maximal tick activity i e late spring and early summer Topping found that about half the cases in the Western states occurred in men over forty whereas half those in the Eastern states were in children under fifteen This age distribution is undoubtedly influenced by propinquity to the wood and dog ticks respectively Mortality increases with age of the patient hence the crude fatality rates in the West are generally higher than those in the East However when corrected for age the rates in comparable groups are similar

Clinical Manifestations *Incubation Period and Prodromata* A history of tick bite is elicited in approximately 80 per cent of patients The incubation period varies between 3 and 12 days with a mean of 7 A short incubation period usually indicates a more serious infection

Onset and Symptoms In nonvaccinated persons the onset is usually abrupt with severe headache a sudden shaking rigor prostration generalized myalgic pains especially localized in the back and leg muscles nausea with occasional vomiting and fever which reaches 103 to 104 F within the first 2 days Pain in the abdominal muscles may be severe and arthralgia is not uncommon Deep muscle palpation often elicits tenderness Occasionally the debut of illness in children and adults is mild accompanied by lethargy anorexia cephalgia and low grade fever These symptoms are similar to those of many acute infectious diseases making specific diagnosis difficult during the first few days

Pyrexia Fever continues for approximately 15 to 20 days in severe cases The febrile course in children may be shorter The pyrexia is high with morning remissions that do not reach normal levels Hyperthermia of 105 F or greater is of unfavorable prognostic significance although fatalities may occur when the patient is hypothermic with concurrent vasomotor collapse Fever generally terminates by lysis over a period of several days but rarely it does so by crisis Recurrent fever is quite uncommon except in the presence of secondary pyogenic complications

The headache is generalized and excruciating and frequently more intense over the frontal area It persists throughout the first and second week of illness in untreated cases Malaise continues for the first week irritability is notable and the patient shuns distractions such as questioning and examination

Cutaneous Manifestations The rash which is present in practically all cases is the most characteristic and helpful diagnostic sign It usually appears on the *fourth* febrile day range 2 to 6 days The initial lesions are on the wrist ankles palms soles and forearms The first lesions are macular nonfixed pink irregularly defined and 2 to 6 mm in width (Plate II) A warm compress applied to the extremity accentuates the rash in the early stages The exanthem is most prominent when the temperature is elevated After 6 to 12 hr the rash extends centripetally to the axilla buttocks trunk neck and face (This is in contrast to the eruption of typhus fever which begins on the trunk and spreads centrifugally rarely involving the face palms or soles) The rash becomes maculopapular after 2 to 3 days (it may be felt by light palpation) and assumes a deeper red hue By about the fourth day it is petechial and fails to fade on pressure Not uncommonly the hemorrhagic lesions coalesce to form large ecchymotic blemishes (Plate II) these lesions tend to form over bony prominences and may ultimately slough to form indolent slow healing ulcers Patients who have had the typical rash show brownish pigmented discolorations at the site of the previous lesions for several weeks during convalescence In milder cases the rash does not become purpuric and may disappear within several days Modern antibiotic therapy may abort the early exanthem whereas the later fixed lesion fades less rapidly under specific therapy

The application of tourniquets for several minutes or the occasional taking of the blood pressure may provoke additional petechiae (Rumpel Leede phenomenon) which is further evidence of capillary abnormalities

Cardiovascular and Respiratory Features During the early stages the pulse is full and regular but accelerated in proportion to the height of the temperature and the blood pressure is well sustained During the peak of illness in seriously ill children and adults the pulse is rapid and feeble and hypotension of 90 mm Hg is common If circulatory failure is long sustained the resultant hypoxia and shock lead to agitation and delirium and contribute to the formation of ecchymoses and gangrene of fingers toes genitalia buttocks earlobes and nose Cyanosis of the peripheral ... of the body is

PLATE II

Rocky Mountain spotted fever (*Upper left*) Typical rash in a four year-old girl on the tenth day (*Upper right*) Purpuric rash in a fatal case (*Lower left*) Yolk sac smear showing intracellular *Rickettsia rickettsii* (Machiavello's stain ×1780) (*Lower right*) Biopsy from scrotum on the twelfth day showing arteriole with mural thrombus and perivascular reaction (×225)

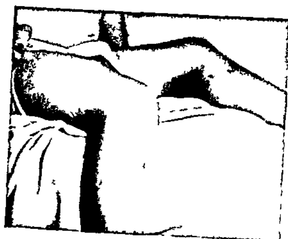
ticks which feed on them during that period of the disease when rickettsemia is occurring

Disease in man is generally acquired from the bite of an infected tick However transmission is unlikely unless the tick remains attached for a number of hours Infection may also be acquired through abrasions in the skin which become contaminated with infected tick feces or tissue juices hence the hazard associated with crushing ticks between the fingers when removing them from persons or animals

There are seasonal variations in the incidence of cases of spotted fever as well as differences in age and sex distribution of cases In each instance these differences are related to exposure to ticks Thus most patients are seen during the period of maximal tick activity i e late spring and early summer *Topping found that about half the cases in the* Western states occurred in men over forty whereas half those in the Eastern states were in children under fifteen This age distribution is undoubtedly influenced by propinquity to the wood and dog ticks respectively Mortality increases with age of the patient hence the crude fatality rates in the West are generally higher than those in the East However when corrected for age the rates in comparable groups are similar

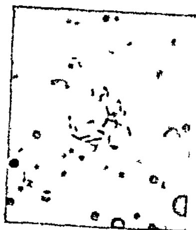
Clinical Manifestations *Incubation Period and Prodromata* A history of tick bite is elicited in approximately 80 per cent of patients The incubation period varies between 3 and 12 days with a mean of 7 A short incubation period usually indicates a more serious infection

Onset and Symptoms In nonvaccinated persons the onset is usually abrupt with severe headache a *sudden shaking rigor prostration generalized myalgic* pains especially localized in the back and leg muscles nausea with occasional vomiting and fever which reaches 103 to 104 F within the first 2 days Pain in the abdominal muscles may be severe and *arthralgia is not uncommon Deep muscle palpation* often elicits tenderness Occasionally the debut of illness in children and adults is mild accompanied by lethargy anorexia cephalgia and low grade fever These symptoms are similar to those of many acute infectious diseases making specific diagnosis difficult during *the first few days*



Pyrexia Fever continues for approximately 15 to 20 days in severe cases The febrile course in children may be shorter The pyrexia is high with morning remissions that do not reach normal levels Hyperthermia of 105 F or greater is of unfavorable *prognostic significance although fatalities may* occur when the patient is hypothermic with concurrent vasomotor collapse Fever generally terminates by lysis over a period of several days but rarely it does so by crisis Recurrent fever is quite uncommon except in the presence of secondary pyogenic complications

The headache is generalized and excruciating and frequently more intense over the frontal area It persists throughout the first and second week of illness in untreated cases Malaise continues for the first week irritability is notable and the patient shuns distractions such as questioning and examination



Cutaneous Manifestations The rash which is present in practically all cases is the most characteristic and helpful diagnostic *sign* It usually appears on the *fourth* febrile day range 2 to 6 days The initial lesions are on the wrist ankles palms soles and forearms The first lesions are macular nonfixed pink irregularly defined and 2 to 6 mm in width (Plate II) A warm compress *applied to the extremity accentuates the rash in* the early stages The exanthem is most prominent when the temperature is elevated After 6 to 12 hr the rash extends centripetally to the axilla but tocks trunk neck and face (This is in contrast to the eruption of typhus fever which begins on the trunk and spreads centrifugally rarely involving the face palms or soles) The rash becomes maculopapular after 2 to 3 days (it may be felt by light palpation) and assumes a deeper red hue By about the fourth day it is petechial and fails to fade on pressure Not uncommonly the hemorrhagic lesions coalesce to form large ecchymotic blemishes (Plate II) these lesions tend to form over bony prominences and may ultimately slough to form indolent slow healing ulcers Patients who have had the typical rash show brownish pigmented discolorations at the site of the previous lesions for several *weeks during convalescence In milder cases* the rash does not become purpuric and may disappear within several days Modern antibiotic therapy may abort the early exanthem whereas the later fixed lesion fades less rapidly under specific therapy

The *application of tourniquets* for several minutes or the occasional taking of the blood pressure may provoke additional petechiae (Rumpel Leede phenomenon) which is further evidence of capillary abnormalities

Cardiovascular and Respiratory Features During *the early stages the pulse* is full and regular but accelerated in proportion to the height of the temperature and the blood pressure is well sustained During the peak of illness in seriously ill children and adults the pulse is rapid and feeble and hypotension of 90 mm Hg is common If circulatory failure is long sustained the *resultant hypoxia and* shock lead to agitation and delirium and contribute to the formation of ecchymoses and gangrene of fingers toes genitalia buttocks earlobes and nose Cyanosis of the peripheral parts of the body is

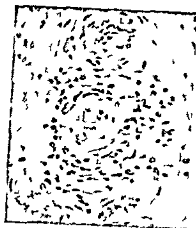


PLATE II

Rocky Mountain spotted fever (*Upper left*) Typical rash in a four-year-old girl on the tenth day (*Upper right*) Purpuric rash in a fatal case (*Lower left*) Yolk sac smear showing intracellular *Rickettsia rickettsii* (Machiavello's stain ×1780) (*Lower right*) Biopsy from scrotum on the twelfth day showing arteriole with mural thrombus and perivascular reaction (×225)

ticks which feed on them during that period of the disease when rickettsemia is occurring

Disease in man is generally acquired from the bite of an infected tick However transmission is unlikely unless the tick remains attached for a number of hours Infection may also be acquired through abrasions in the skin which become contaminated with infected tick feces or tissue juices hence the hazard associated with crushing ticks between the fingers when removing them from persons or animals

There are seasonal variations in the incidence of cases of spotted fever as well as differences in age and sex distribution of cases In each instance these differences are related to exposure to ticks Thus most patients are seen during the period of maximal tick activity i e late spring and early summer Topping found that about half the cases in the Western states occurred in men over forty whereas *half those in the Eastern states* were in children under fifteen This age distribution is undoubtedly influenced by propinquity to the wood and dog ticks respectively Mortality increases with age of the patient hence the crude fatality rates in the West are generally higher than those in the East However when corrected for age the rates in comparable groups are similar

Clinical Manifestations ***Incubation Period and Prodromata*** A history of tick bite is elicited in approximately 80 per cent of patients The incubation period varies between 3 and 12 days with a mean of 7 A short incubation period usually indicates a more serious infection

Onset and Symptoms In nonvaccinated persons the onset is usually abrupt with severe headache a *sudden shaking rigor prostration* generalized myalgic pains especially localized in the back and leg muscles nausea with occasional vomiting and fever which reaches 103 to 104 F within the first 2 days Pain in the abdominal muscles may be severe and arthralgia is not uncommon Deep muscle palpation often elicits tenderness Occasionally the debut of illness in children and adults is mild accompanied by lethargy anorexia cephalgia and low grade fever These symptoms are similar to those of many acute infectious diseases making specific *diagnosis difficult during the first few days*

Pyrexia Fever continues for approximately 15 to 20 days in severe cases The febrile course in children may be shorter The pyrexia is high with morning remissions that do not reach normal levels Hyperthermia of 105 F or greater is of unfavorable prognostic significance although fatalities may *occur when the patient is hypothermic with* concurrent vasomotor collapse Fever generally terminates by lysis over a period of several days but rarely it does so by crisis Recurrent fever is quite uncommon except in the presence of secondary pyogenic complications

The headache is generalized and excruciating and frequently more intense over the frontal area It persists throughout the first and second week of illness in untreated cases Malaise continues for the first week irritability is notable and the patient shuns distractions such as questioning and examination

Cutaneous Manifestations The rash which is present in practically all cases is the most characteristic and helpful diagnostic sign It usually appears on the *fourth* febrile day range 2 to 6 days The initial lesions are on the wrist ankles palms soles and forearms The first lesions are macular nonfixed pink irregularly defined and 2 to 6 mm in width (Plate II) A warm compress applied to the extremity accentuates the rash in the early stages The exanthem is most prominent when the temperature is elevated After 6 to 12 hr the rash extends centripetally to the axilla buttocks trunk neck and face (This is in contrast to the eruption of typhus fever which begins on the trunk and spreads centrifugally rarely involving the face palms or soles) The rash becomes maculopapular after 2 to 3 days (it may be felt by light palpation) and assumes a deeper red hue By about the fourth day it is petechial and fails to fade on pressure Not uncommonly the hemorrhagic lesions coalesce to form large ecchymotic blemishes (Plate II) these lesions tend to form over bony prominences and may ultimately slough to form indolent slow healing ulcers Patients who have had the typical rash show brownish pigmented discolorations at the site of the previous lesions for several weeks during *convalescence* In milder cases the rash does not become purpuric and may disappear within several days Modern antibiotic therapy may abort the early exanthem whereas the later fixed lesion fades less rapidly under specific therapy

The application of tourniquets for several minutes or the occasional taking of the blood pressure may provoke additional petechiae (Rumpel Leede phenomenon) which is further evidence of capillary abnormalities

Cardiovascular and Respiratory Features During *the early stages the pulse is full* and regular but accelerated in proportion to the height of the temperature and the blood pressure is well sustained During the peak of illness in seriously ill children and adults the pulse is rapid and feeble and hypotension of 90 mm Hg is common If circulatory failure is long sustained the resultant hypoxia and shock lead to agitation and delirium and contribute to the formation of ecchymoses and gangrene of fingers toes genitalia buttocks earlobes and nose Cyanosis of the peripheral parts of the body is

common venous pressure determinations do not reveal elevations indicative of congestive heart failure per se nor is the venous pressure elevated following the careful administration of intravenous fluids A reduction of the total blood volume is occasionally found as are evidences of myocardial impairment as shown by electrocardiography i e low voltage of ventricular complexes minor ST segment deflections and occasionally delay in AV conduction time (Harrell) These changes are transient and similar to those encountered in patients with pneumonia typhoid fever or uremia Severely ill patients present a puffy appearance of the face hands ankles feet and lower sacrum

Respirations are either normal or slightly accelerated Cough may be harassing and nonproductive and localized pneumonitis may occur whereas pulmonary consolidation is extremely uncommon Pulmonary edema may develop particularly after the injudicious use of intravenous fluids

Hepatic and Renal Manifestations In the majority of moderately ill patients there is little alteration in the renal or hepatic function The liver may be enlarged but jaundice is unusual Oliguria commonly occurs in the seriously ill and anuria may mark the critical case Azotemia is common but when marked is a very unfavorable sign Abnormalities in liver function are probably responsible for the hypoproteinemia with reduction in the albumin fraction

Neurologic Manifestations The principal neurologic manifestations are headache restlessness and varying degrees of insomnia Stiffness of the back is common The cerebrospinal fluid is clear with normal dynamics and normal chemical constituents Coma and muscular rigidity may occur Athetoid movements convulsive seizures and hemiplegia are grave manifestations Deafness during the active stages of the disease is not uncommon As a rule all neurologic signs abate without residual Recent findings based upon follow up examinations and electroencephalograms may be interpreted as indicative of minor residual brain damage for a year or more following recovery of certain patients from Rocky Mountain spotted fever

Other Physical Manifestations Patients become dehydrated with extreme dryness of lips gums tongue and pharynx The skin is hot and dry and the conjunctivae are frequently injected and the eyes suffused Photophobia is common in the early stages of illness Petechial hemorrhages may be noted in the conjunctivae or in the retina The spleen is enlarged in approximately one half the cases and is firm and nontender Abdominal distention is frequent and occasionally some degree of intestinal ileus is observed Constipation is usual

Course of Disease In mild and moderately severe cases the disease abates within 2 weeks and convalescence is rapid In fatal cases death usually occurs during the latter part of the second week as a result of toxemia vasomotor weakness and shock or renal failure with azotemia

In vaccinated individuals who contract the disease the illness is mild with a short febrile course and an atypical rash

Complications and Prognosis If the serious manifestations of spotted fever mentioned above are regarded as intrinsic parts of the disease then complications are uncommon and consist mainly of secondary bacterial infections viz bronchopneumonia otitis media and parotitis Thrombosis of major blood vessels may result in gangrene of a portion of an extremity Hemiplegia and peripheral neuritis are important but rare sequelae

The over all mortality rate for spotted fever was formerly about 20 per cent Fatal outcome occurred in more than half of persons over forty years of age but was appreciably lower in children and young adults Since the introduction of the broad spectrum antibiotics and the development of more precise knowledge regarding correction of the physiologic abnormalities which develop during the disease deaths rarely occur from this infection even among the patients who first come under medical care rather late in the disease

Differential Diagnosis During the early stages of infection before the rash has appeared differentiation from other acute infections is difficult History of tick bite while living or traveling in a highly endemic area is helpful The rash of meningococcemia resembles Rocky Mountain spotted fever in certain aspects since it is macular or maculopapular or petechial in the chronic form and petechial confluent or ecchymotic in the fulminant type The meningococcic skin lesion is tender and develops with extreme rapidity in the fulminant form whereas the rickettsial rash occurs on about the fourth day of disease and gradually becomes petechial The exanthem of rubella rapidly becomes confluent while that of rubeola almost never becomes petechial The exanthem of varicella or variola is first erythematous and later becomes vesicular The rose spots of typhoid fever are usually on the lower chest or abdomen and remain delicate without hemorrhagic character Rocky Mountain spotted fever skin lesions in contrast to those of typhoid begin on the periphery of the body and later become petechial The rash of infectious mononucleosis is usually morbilliform on the trunk and rarely becomes petechial Angina lymphadenopathy and atypical lymphocytes in the blood are differentiating features

Murine typhus is a milder disease than Rocky

Table 95 EFFECT OF SPECIFIC ANTIBIOTICS ON THE COURSE OF THE MAJOR RICKETTSIOSES

Disease	Untreated		Treated	
	Average duration of fever days	Mortality per cent	Average duration of fever after Rx, days	Mortality per cent
Rocky Mountain spotted fever	16	21	3	0
Epidemic typhus	14	30	2	0
Murine typhus	12	2	2	0
Scrub typhus	14	15	1	0

tube and elixir of oxytetracycline containing 250 mg per ml is available Oxytetracycline hydrochloride when mixed with a sodium glycinate buffer is a stable solution suitable for intravenous administration A daily dose of 1 0 Gm suffices

Table 95 summarizes information on the duration of disease and the mortality in the major rickettsioses prior to and since the introduction of specific antibiotic therapy

Duration of Therapy and Therapeutic Response Therapy with antibiotics is continued until the toxemia has abated the general condition has markedly improved and the temperature has remained at normal levels for 24 hr In uncomplicated cases of spotted fever there is symptomatic improvement within 24 hr and normal temperature in 60 to 72 hr

Figure 143 illustrates the typical response in a moderately ill adult in whom specific therapy was augmented by a moderate supportive regimen Fig

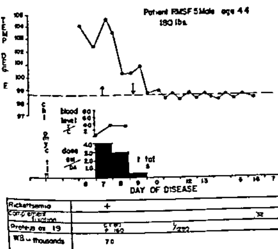

Fig. 143 Rocky Mountain spotted fever Course of illness in a moderately ill adult patient treated with chloramphenicol. Patient became afebrile in 2 5 days

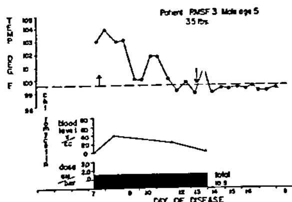

Fig 144 Rocky Mountain spotted fever Clinical course in a severely ill, semicomatose boy who received energetic supportive therapy as well as chloramphenicol. The temperature reached normal levels 6 days after treatment was instituted Convalescence was uncomplicated

ure 144 summarizes the findings in a severely ill child who required a longer course of antibiotic treatment as well as vigorous supportive care

Supportive Care *Nursing Care* Frequent turning of the patient relieves pressure from prominent bony parts such as the lower spine hip elbows and heels thereby lessening superficial skin lesions In comatose patients frequent turning also militates against the development of hypostatic pneumonia Proper mouth hygiene with frequent swabbing of the oral cavity may avert the development of parotitis and gingivitis Sucking of the juice of a lemon or the oral use of glycerin or mineral oil is helpful

Protein Balance A generous intake of protein should be provided by frequent feedings as soon as the disease is suspected in order to avoid subsequent protein deficiency Usually food is well tolerated by patients with rickettsial disease and the daily diet should provide from 3 to 5 Gm protein per kg normal body weight, with adequate carbohydrate and fat to make it palatable When the patient is uncooperative the diet may be supplemented by hourly liquid protein feedings via stomach tube

At the critical stage when hypoproteinemia is present and changes in capillary permeability lead to edema and vascular embarrassment, careful attention is given to the parenteral administration of protein supplements When indicated by hematologic studies whole-blood transfusions given slowly are helpful or if the total red cell mass is adequate one of the preformed protein supplements is bene-

Mountain spotted fever the rash is less extensive nonpurpuric nonconfluent and renal and vascular complications are uncommon Not infrequently differentiation of these two rickettsial infections must await the results of specific serological tests Epidemic typhus fever is capable of causing all the pronounced clinical physiologic and anatomic alterations seen in patients with Rocky Mountain spotted fever i e hypotension peripheral vascular failure cyanosis skin necrosis and gangrene of digits renal failure with azotemia and neurological manifestations However the rash of classical typhus is noted initially in the axillary folds and on the trunk and later extends peripherally rarely involving the palms soles or face The serologic patterns in these two diseases are distinctive when specific rickettsial antigens are employed in tests Moreover louse borne typhus is not recognized in the United States except in the form of Brill s disease (recurrent typhus fever) Rickettsialpox although caused by a member of the spotted fever group of organisms is usually readily differentiated from Rocky Mountain spotted fever by the initial lesion the relative mildness of the illness and the early vesiculation of the maculopapular rash The Weil Felix reaction is positive in Rocky Mountain spotted fever and in murine and epidemic typhus but is negative in rickettsialpox Agglutinins against *Proteus* OX 19 and OX 2 appear in the serum of patients with spotted fever but only those against OX 19 are found in murine and epidemic typhus

Therapy

General Certain physiochemical changes occurring in the patient seriously ill with one of the diseases of the typhus spotted fever group should be understood before outlining a therapeutic regime These changes are circulatory collapse coma oliguria and anuria azotemia anemia hypoproteinemia hypochloremia and edema of the underlying tissues These alterations are often absent in the mildly ill and in them management is much less complicated The therapeutic principles necessary for the treatment of all rickettsioses are (1) specific chemotherapy and (2) supportive care Attention to both is mandatory for the seriously ill patient first recognized late in the disease Contrariwise during the first week and in the moderately ill patient supportive therapy may be less energetic since specific chemotherapy usually suffices The early mild case may be successfully treated at home whereas the later case should receive hospital care

Therapeutic measures advisable for the management of Rocky Mountain spotted fever will be described in detail Variations of this regimen which apply to the other rickettsioses are described in subsections relegated to other diseases of the typhus-spotted fever group and Q fever

Specific Therapy Specific therapy is most effective when initiated during the early stages of disease coincident with the appearance of the rash When therapy is delayed until the rash has become hemorrhagic and widespread the response is less dramatic The antibiotics of choice are chloramphenicol chlortetracycline and oxytetracycline which are effective because of their rickettsiostatic properties They are not rickettsiocidal Each of the antibiotics is supplied for oral and intravenous use

Chloramphenicol (*Chloromycetin*) The initial oral dose is calculated on the basis of 50 mg per kg body weight and subsequent doses of 1 0 Gm are given every 8 hr or 0 5 Gm every 4 hr for adults Daily requirement for children is calculated on the basis of 75 mg per kg body weight per day Chloromycetin hydrochloride available in 0 5 Gm ampuls may be given intravenously on a schedule of 0 5 Gm every 6 hr to adults This solution is incorporated in either 5 per cent glucose or in physiologic saline in volumes not exceeding 200 ml The direct intravenous administration of the undiluted suspension is not advised Chloramphenicol powder obtained from the gelatin sealed capsules may be suspended in saline or distilled water for administration via stomach tube Chloromycetin palmitate a palatable liquid preparation suitable for children may be given for maintenance therapy calculated on the basis of 100 mg per kg body weight per day divided in equal doses at 6 to 8 hr intervals

Chlortetracycline The initial oral dose is calculated on the basis of 25 mg per kg body weight Subsequent daily doses of 25 mg per kg body weight are divided equally and given at 4 to 6 hr intervals The 4 hr schedule reduces the tendency to nausea and the concurrent administration of milk or semisolid nourishment is desirable Chlortetracycline hydrochloride with a sodium glycinate buffer is prepared in 100 mg vials for intravenous therapy It is administered on the basis of 5 to 10 mg per kg body weight per day divided in equal doses at 6 hr intervals although 100 mg every 6 hr usually suffices The buffered antibiotic is dissolved in 10 ml of sterile water or physiologic saline for intravenous administration Care should be exercised in preventing perivascular extravasation and the chemical phlebitis that might result

Oxytetracycline The initial oral dose is calculated on the basis of 25 mg per kg body weight Subsequent daily doses of 25 mg per kg body weight are given at intervals of 4 to 6 hr Children require doses of 25 to 50 mg per kg body weight per day Oxytetracycline powder may be suspended in distilled water for administration by stomach

161 RICKETTSIALPOX

T E Woodward and J E Smadel

Definition Rickettsialpox is a mild nonfatal self limited acute febrile illness caused by *Rickettsia akari* which is transmitted from mouse to man by mites It is characterized by an initial skin lesion at the site of the mite bite a weeks febrile course and a papulovesicular rash

Etiology and Epidemiology Rickettsialpox was first recognized in New York City in 1946 and later in several areas in New England It has an annual incidence of approximately 200 cases The vector is a small colorless mite *Allodermanyssus sanguineus* (Hirst) which infests small mice and rodents House mice serve as the reservoir of infection

Rickettsia akari is morphologically and biologically similar to other rickettsiae and is antigenically related to but distinct from *R rickettsii* the cause of Rocky Mountain spotted fever Mice guinea pigs and fertile hens eggs are susceptible to experimental infection and diagnostic antigens prepared from infected yolk sacs are used in complement fixation tests

Clinical Manifestations The initial skin lesion appears about 7 to 10 days after the mite bite as a firm red papule 1 to 1 5 cm in diameter In a few days the center vesiculates and the papule is surrounded by an area of erythema The regional lymph glands are moderately enlarged The primary lesion which is never painful becomes covered with a black scab it heals slowly and a small scar is visible on separation of the crust

The febrile phase begins 3 to 7 days following the initial lesion and a body exanthem may accompany the fever or begin several days later The onset of fever is sudden with chilly sensations or frank chills headache sweats myalgia anorexia and photophobia The pyrexia ranges from 103 to 104 F and continues for about a week occasionally with morning remissions

The exanthem is maculopapular vesicular generalized in distribution and may be abundant or scant The lesions may involve the oral cavity but not the palms or soles In a week the vesicles dry and form scabs which eventually scale but leave no scar

The constitutional symptoms are generally mild and the course of illness uncomplicated No fatal cases have been reported

The disease may be confused with varicella (chickenpox) which is different in that it occurs usually in childhood and has no initial lesion and the papular cutaneous lesion is entirely transformed into a vesicle Variola (smallpox) is accompanied by a more severe constitutional reaction and the vesicles become pustules The skin lesions of the other rickettsioses differ in their lack of vesiculation The Weil Felix reaction remains negative in this rickettsial disease but the specific complement fixation test is a useful laboratory diagnostic aid even though there is considerable crossing with materials from Rocky Mountain spotted fever

Treatment and Prevention Chloramphenicol chlortetracycline and oxytetracycline are all effective for treating patients with rickettsialpox The temperature reaches normal levels in about 2 days and recovery is rapid The therapeutic procedures are comparable to those used in spotted fever which are described in detail on p 1028

Control measures should be directed toward elimination of house mice and the vector mites responsible for transmitting the disease

ficial Intravenous albumin may be particularly useful since it also aids in the reduction of tissue edema The judicious administration of one of the plasma expanders at this stage may have a definite favorable effect upon the impending circulatory collapse If the patient is anuric and azotemia is pronounced overloading the circulation with protein supplements and fluids is to be avoided The *type and amount of parenteral therapy should be* governed entirely by clinical judgment and very careful laboratory studies Frequent determinations of hemoglobin hematocrit electrolytes and protein sometimes at intervals of a few hours during crucial periods are necessary in order to ascertain abnormalities and to permit institution of corrective measures

Fluid Balance Special attention should be given to the total daily fluid requirement In the presence of coma 3 to 5 liters of parenteral fluids may be required particularly in severely dehydrated patients Using the laboratory results as a guide intravenous physiologic saline may be used to correct the hypochloremia As a rule the proper administration of intravenous saline and glucose infusions will correct the electrolytic imbalance Efforts should be directed toward ensuring a daily urinary output of approximately 1 500 ml Too rapid administration of intravenous fluids may provoke additional tissue edema and greatly increase the load upon a weakened myocardium

Complications

Pyogenic complications including otitis media and parotitis are encountered in patients severely ill with Rocky Mountain spotted fever and other rickettsioses These localized infections respond to therapy with the broad spectrum antibiotics when combined with ordinary supplemental surgical *measures The sulfonamides are unnecessary* for treatment of pyogenic complications and actually exert a detrimental effect upon the course of rickettsial infections

Pneumonitis usually develops as a result of specific rickettsial action The sputum is scant but should be examined to determine whether superimposed infection is present Specific therapy is guided by the results of these laboratory studies The pneumonitis generally responds to the antibiotic therapy already outlined and penicillin or supplemental antibiotics are rarely required for secondary bacterial pneumonia

Circulatory failure of peripheral or central origin is combatted by careful administration of elec*trolytic and protein supplements as described* Myocardial failure may develop as a result of overzealous intravenous alimentation and is recognized by the common signs of rapid pulse gallop rhythm increase in venous pressure and muffled cardiac sounds This *complication under present regimens* is unusual When the clinical signs reveal unmistakable evidence of cardiac failure digitalis may be employed in the usual manner Oxygen therapy by nasal tube mask or tent improves the cardiac and circulatory status and is helpful in hypoxic patients with involvement of the central nervous system

Prevention

Prevention is attained primarily by avoidance of tick infested areas When this is impractical personal prophylactic measures include (1) the wearing of clothing which interferes with attachment of ticks i e boots and a one-piece outer garment preferably impregnated with one of the tick repellents such as N n butyl acetanilide and (2) daily inspection of the entire body including the hairy parts to detect and remove attached ticks In removing attached ticks great care should be taken to avoid crushing the arthropod with resultant contamination of the bite wound touching the tick with gasoline or whiskey encourages detachment but gentle traction with tweezers applied close to the mouth parts may be necessary the skin area should be disinfected with soap and water or other antiseptics Similarly precautions should be employed in removing engorged ticks from dogs and other animals since infection through minor abrasions on the hands is possible Vaccines containing *R rickettsii* are available commercially and *should* be used *for those exposed to great risk* viz persons frequenting highly endemic areas and laboratory workers exposed to the agent Since the broad spectrum antibiotics were shown to be such excellent therapeutic agents in spotted fever there has been less impetus for vaccination of persons who run only a minor risk of infection

a toxic factor which is lethal to mice and rats and may be neutralized by convalescent serum from man or lower animals

The common vector of *R mooseri* for rats and man is the rat flea (*Xenopsylla cheopis*) Blanc is of the opinion that infection may be spread from man to man by the pest flea (*Pulex irritans*) In nature the rat louse (*Polyplax spinulosis*) may transmit the agent among rodents Customarily rat fleas become infected on ingestion of blood from diseased rats the rickettsiae multiply within the intestinal cells of the arthropod and are excreted in the feces Infection in man occurs following the flea bite and contamination of the broken skin by rickettsia laden feces Dried flea feces may infect via the conjunctivae or upper respiratory tract

Rats and mice are naturally infected with murine typhus and although the rodent disease is nonfatal viable rickettsiae persist in the brain for variable periods

Murine typhus is one of the most benign and widespread of the rickettsioses in the United States Prevalent in the Southeastern and Gulf Coast states it has been identified in most of the other states and in harbor centers throughout the world wherever rats and fleas abound Through control of rats and their fleas a sharp decline in incidence has occurred since 1951 particularly in the Southern United States In urban areas the disease is more prevalent during the summer and fall months and occurs predominantly among persons working in proximity to granaries or food depots Recently there has been an extension to certain rural areas because changing agricultural practices have provided rats with ready access to adequate food supplies

Clinical Manifestations *Incubation Period and Prodromata* Based upon experimental observations the incubation period ranges from 8 to 16 days with a mean of 10 Common prodromata are headache backache arthralgia and chilly sensations Nausea malaise and insufficient temperature rises may actually precede the true onset of disease

Onset and General Symptoms A frank shaking chill and often repeated rigors are present at onset associated with a severe frontal headache and fever This triad of headache chill and pyrexia is usually followed within a few hours by nausea and vomiting Prostration malaise and weakness are sufficient to enforce cessation of activity in adults in contrast to children whose illness is less severe Occasionally mild symptoms make it difficult to define the actual onset

Pyrexia The usual febrile course in murine typhus lasts for about 12 days in adults and the temperature ranges from 102 to 104 F but may reach 105 to 106 F in children The temperature may reach high levels abruptly after onset or ascend in a stepwise manner during the first few days With the appearance of the rash fever is usually sustained with partial daily remissions which occasionally reach normal levels in the morning Defervescence is generally by lysis over several days but sometimes occurs by abrupt crisis Transient mild fever of 100 F is not uncommon during early convalescence A few patients experience only low grade fever throughout but this does not necessarily connote a mild illness

Cutaneous Manifestations The early lesions which are sparse and discrete are hidden in the axillae and inner surface of the arm Most patients then develop with surprising suddenness a generalized dull red macular rash of the upper abdomen shoulders chest arms and thighs The individual lesions are discrete and pea size with an ill defined border and fade on pressure during the first 24 hr They later become maculopapular in contrast to the exanthem of epidemic typhus which is persistently macular The distribution over the trunk with sparse involvement of the extremities palms soles and face differs from the peripheral distribution and facial involvement of Rocky Mountain spotted fever The murine rash generally appears initially on the fifth febrile day but rarely is it seen concurrently with the onset or developing as late as the seventh day

Eighty per cent of patients develop a rash which usually persists for 4 to 8 days and fades before defervescence The cutaneous manifestations vary greatly in intensity and duration and may be fleeting They are readily overlooked in dark skinned patients in whom they should be searched for by light palpation and indirect lighting

Cardiovascular and Respiratory Features An irritating nonproductive cough is frequent and is occasionally associated with moderate hemoptysis Early in the second week rales may be detected in the basilar lung areas These changes are generally rickettsial rather than bacterial in origin and respond to the broad spectrum antibiotics but not to penicillin or sulfonamide therapy Pulmonary congestion occurs in extremely ill and elderly patients

Accelerated pulse hypotension and general circulatory weakness occur in this disease although less frequently than in patients with the more severe epidemic typhus or Rocky Mountain spotted fever The reader is referred to the chapter on Rocky Mountain spotted fever (Chap 160) relative to the details of the cardiovascular features

Neurologic Manifestations Headache is the most common neurologic manifestation of murine typhus and may dominate the clinical picture It is frontally localized and continues into the second week of illness In the early stages the facial expression is strained and the patient resents distraction Stupor

162 AFRICAN TICK BORNE FEVER

T E Woodward and J F Smadel

Definition African tick borne fever also called *boutonneuse fever South African tick bite fever* is a mild to moderately severe nonfatal illness characterized by an initial lesion (called the *tache noir* in boutonneuse fever) fever of several days to 2 weeks and a generalized maculopapular erythematous rash which appears on about the fifth day and usually involves the palms and soles Specific complement fixing antibodies appear in the patient s serum during convalescence but agglutinins to *Proteus* OX 19 (Weil Felix reaction) are frequently found only in low titer

Etiology and Epidemiology The causative agent *Rickettsia conorii* is a member of the spotted fever group of rickettsiae and is transmitted to man by infected ticks In the Mediterranean area the bite of infected *Rhipicephalus sanguineus* the brown dog tick is responsible whereas in South Africa a number of ticks are assumed to be vectors viz *Haemaphysalis leachi Amblyomma hebraeum Rhipicephalus appendiculatus Boophilus decoloratus* and *Hyalomma aegyptium*

The disease occurs in the Mediterranean and Black Sea area and in Africa but not in the Western Hemisphere It is more prevalent during summer months in temperate zones whereas it occurs throughout the year in the tropics

Clinical Manifestations The clinical course is usually milder than in spotted fever with a shorter febrile period and fewer severe complications Fatalities are few and generally limited to the aged or debilitated The initial lesion heals slowly and the regional lymph nodes are enlarged The rash usually remains papular and rarely becomes hemorrhagic as it does in spotted fever

Treatment and Prevention Chloramphenicol chlortetracycline and oxytetracycline are equally effective therapeutic agents for African tick borne fever Patients generally become afebrile after two days of treatment and recovery is rapid The therapeutic procedures are comparable to those used in spotted fever which are described in detail on p 1028

The major effective methods of control are concerned with avoidance of tick bites these include application of newer repellents and prompt removal of attached ticks Effective vaccines are not available commercially

163 MURINE (ENDEMIC) TYPHUS FEVER

T E Woodward and J E Smadel

Definition Murine typhus fever is an acute specific febrile disease caused by *Rickettsia mooseri* and transmitted to man by fleas The clinical illness is characterized by fever of 9 to 14 days headache a maculopapular rash appearing on the third to fifth day myalgia moderate neurologic manifestations and the appearance during convalescence of agglutinins for certain strains of *Proteus* bacteria (Weil Felix reaction) and of specific complement fixing antibodies which react with the causal rickettsiae Treatment with the broad spectrum antibiotics is highly efficacious

Etiology and Epidemiology *Rickettsia mooseri* resembles other rickettsiae as regards morphologic properties staining characteristics and intracellular parasitism Under the electron microscope *R mooseri* contains dense masses of nuclear material in a less dense homogeneous protoplasmic substance the whole of which is surrounded by a limiting membrane It differs from *R rickettsii* in that it always multiplies within the cytoplasm of cells in contrast to the intranuclear and cytoplasmic positions of spotted fever rickettsiae

Invasion of the body by *R mooseri* provokes specific and nonspecific immunologic responses Utilizing highly purified antigens specific antibodies may be demonstrated readily by complement fixation and agglutination reactions The positive Weil Felix reaction which occurs in this disease is essentially nonspecific since it is attributable to the presence of a common carbohydrate antigen in *Proteus* OX 19 and *R mooseri* and since the reaction is also positive in epidemic typhus and spotted fever A number of investigators have demonstrated group specific rickettsial antigens common to both *R mooseri* and *R prowazeki* viz a heat stable complement fixing substance Furthermore both murine and epidemic rickettsiae possess

ing antibodies in convalescence The broad spectrum antibiotics are specific therapeutic agents

Etiology and Epidemiology The causative microbe *R prowazeki* is closely related to *R mooseri* which causes murine typhus indeed the two have a number of common antigens *Rickettsia prowazeki* was the first of the rickettsiae shown to have its own enzyme system which permits it to respire independently of the host cell (Bovarnick and Snyder 1949)

Man generally is infected when rickettsia laden louse feces are rubbed into the broken skin scratching the louse bite facilitates this process *Pediculus humanus corporis* which is peculiarly adapted to man is the only important vector of epidemic typhus It dies of its infection and fails to transmit rickettsiae to its offspring There is no known animal habitat of *R prowazeki* it is maintained by a cycle involving man louse man New epidemics apparently originate from patients with Brill s disease (recurrent epidemic typhus) Inhalation of dust containing dried louse feces may rarely cause infection

Epidemic typhus if uncontrolled behaves as a cyclic disease in a susceptible population extending over a 3 year period During the first year there is a gradual seeding of cases throughout the group during the second there is epidemic spread and during the third the epidemic tapers off because the majority of persons have already become immune Outbreaks of epidemic typhus last occurred in the United States in the nineteenth century and its presence is now recognized only in the form of Brill s disease (see p 1036)

Clinical Manifestations A classic clinical description of Old World typhus is provided in Wolbach Todd and Palfrey s monograph of 1922 Epidemic typhus resembles murine typhus but is more severe After an incubation period of about 7 days an abrupt onset of headache chill and rapidly mounting fever ushers in the illness Cephalgia malaise and prostration continue unabated until the rash appears on the fifth febrile day It is initially macular in the axillary folds but ultimately invades the trunk and extremities as a pink irregular macular lesion which becomes fixed petechial and confluent in the later stages

Neurologic features range from headache and general spasticity to extreme agitation stupor and coma Circulatory disturbances consisting of tachycardia hypotension and cyanosis are more profound than those observed in murine typhus and are almost as severe as in Rocky Mountain spotted fever Ultimately in untreated cases azotemia often reaches high levels as a result of vascular and renal failure and death occurs late in the second week of illness Furthermore thrombosis of major blood vessels and cutaneous gangrene develop in a manner similar to that seen in the virulent form of Rocky Mountain spotted fever

The complications and sequelae in epidemic typhus are more severe than those in murine typhus but not as severe as those in Rocky Mountain spotted fever However during certain outbreaks epidemic typhus was fatal to 60 per cent of those infected and convalescence in survivors was prolonged Broad spectrum antibiotics have essentially *eradicated mortality in this dread disease provided* therapy is instituted before irreversible changes have been established in the tissues

Differential Diagnosis Differentiation of epidemic typhus from the various rickettsioses and other diseases with which it may be confused is described in Chap 160 Rocky Mountain Spotted Fever The disease in epidemic form never occurs in the absence of lousiness in the general population Under the conditions in which typhus epidemics are likely to occur other diseases which may cause confusion include malaria relapsing fever pneumonia and tuberculosis Classic typhus contracted by a previously vaccinated person is usually mild and may be clinically indistinguishable from murine typhus except by serologic methods

Treatment and Prevention Chloramphenicol chlortetracycline and oxytetracycline have each been found to be highly efficient therapeutic agents in epidemic typhus Usually the patient becomes afebrile after 2 days of treatment The therapeutic procedures are comparable to those used in spotted fever which are described in detail on p 1028

The most effective measures for controlling epidemic typhus are those which eliminate lousiness DDT with its long lasting effect when dusted into clothing is ideal for this purpose In certain areas e g Korea where DDT resistant lice are found lindane powder is effective

A commercially available vaccine prepared from formalin treated infected yolk sac tissue is an effective immunizing agent

Wolbach S B J L Todd and F W Palfrey The

and prostration may occur in the second week and in severe cases there may be muttering delirium and extreme agitation and coma similar to the more severe louse borne typhus Coma in elderly patients after two weeks of illness presages death Nuchal rigidity and general spasticity often suggest meningitis although the spinal fluid is essentially normal except for slight increases in pressure and lymphocytes (5 to 30 per cu mm) Transient partial deafness occurs occasionally in murine typhus patients but rarely is there localized neuritis or hemiplegia Neurologic sequelae are unusual Children experience minimal neurologic changes

Other Physical Manifestations During the first two days of illness the patient may be nauseated and vomit but vomiting later in the illness should arouse suspicion of an intercurrent complication Abdominal pain particularly in dehydrated patients is bothersome and when associated with diarrhea responds to intravenous alimentation A sluggish constipated bowel is occasionally observed Hepatomegaly and jaundice are unusual There is splenomegaly in approximately 25 per cent of patients

Photophobia retroocular pain suffusion of the eyes and congestion of the conjunctivae are common manifestations but are less severe than in the other typhus and spotted fevers Dehydrated patients often have a furred brown tongue and crusting of the gums and mucous membranes

Renal function is usually unaltered except in elderly patients with prolonged hypotension and vascular weakness Under these circumstances in seriously ill patients azotemia may develop to the degree observed in epidemic typhus The blood chlorides are low in severe murine typhus as in the epidemic type hypochloremia of 80 mEq per liter may be observed Hypoproteinemia resulting from lowered serum albumin is encountered

Course of Disease and Complications After defervescence murine typhus patients recover rapidly Fatalities occur between the ninth and twelfth days in elderly or debilitated patients usually as a result of circulatory and renal failure thrombosed blood vessels or intercurrent infection

Complications are usually pyogenic such as otitis media and parotitis and a superimposed pneumonitis may be difficult to differentiate from pulmonary congestion Fortunately the average course of murine typhus fever is uncomplicated

Prognosis The mortality in murine typhus was low even before the introduction of modern specific therapy Only one death occurred in the 114 cases studied by Maxcy and none in the 180 reported by Stewart and Pullen

Differential Diagnosis See the discussion in the chapter on Rocky Mountain spotted fever (p 1027) The geographic and seasonal occurrence of murine typhus and spotted fever differ and may help in diagnosis

Treatment and Prevention The therapeutic procedures are comparable to those used in spotted fever which are described in detail on p 1028 Chloramphenicol chlortetracycline and oxytetracycline promptly control the disease

Prevention of murine typhus in man is attained by reducing the natural reservoir and vector by applying measures for eliminating rodents and employing DDT in rat infested areas to control fleas

164 EPIDEMIC (LOUSE BORNE) TYPHUS FEVER

T E Woodward and J E Smadel

Definition The classical epidemic form of typhus is a severe acute febrile disease caused by *Rickettsia prowazeki* and transmitted to man by the body louse Intense headache continuous pyrexia of about 2 weeks a macular skin eruption appearing on about the fifth febrile day malaise and vascular and neurologic disturbances represent the principal clinical features Confirmation of the diagnosis is made by demonstration of *Proteus* OX 19 agglutinins and of specific complement fix

modern therapeutic methods deaths are extremely rare and convalescence is short

Differential Diagnosis Scrub typhus is to be differentiated from the other members of the typhus and the spotted fever group of diseases as well as from measles typhoid fever and meningococcal infections (see Chap 160 Rocky Mountain Spotted Fever) The geographic localization of scrub typhus the primary lesion and the occurrence of OXK agglutinins are especially useful in establishing the diagnosis

Treatment and Prevention Chloramphenicol chlortetracycline and oxytetracycline are valuable specific therapeutic agents in scrub typhus The therapeutic procedures are comparable to those used in spotted fever which are described in detail on p 1028 In fact scrub typhus is more amenable to drugs than are the other rickettsial infections since patients with this disease regularly become afebrile within 24 to 36 hr after beginning treatment irrespective of the stage of disease

Prevention of disease in the individual is accomplished by the application of miticidal chemicals (dibutyl phthalate benzyl benzoate and others) to clothing and the skin There is no satisfactory vaccine

167 Q FEVER

T E Woodward and J E Smadel

Definition Q fever is an acute infectious disease caused by *Rickettsia burnetii* and characterized by a sudden onset of fever malaise headache weakness anorexia and usually an interstitial pneumonitis Rickettsemia occurs during the febrile period and specific complement fixing antibodies are present during convalescence In contrast to the other rickettsioses the disease is not associated with a cutaneous exanthem or agglutinins for the proteus bacteria (Weil Felix reaction)

Etiology and Epidemiology *Rickettsia burnetii* (Derrick 1939) possesses the general properties of other rickettsiae but is somewhat more resistant to inactivation in unfavorable environments and more pleomorphic than the others Its infectivity after drying under natural conditions is of importance in the spread of infection to man Its pleomorphism which ranges from diplobacillary structures measuring 1 5 μ in length to tiny spheres about 0 2 μ in diameter contributes to its filterability through Berkefeld N candles This filterability led Cox (1939) to suggest the name *R diaporica* for the first American isolate but the name was subsequently abandoned when this agent was found to be identical with that causing Q fever in Australia *R burnetii* has a wide host range in nature but guinea pigs and embryonated eggs are the common laboratory hosts employed for its propagation

Human cases of Q fever are contracted by inhalation of infected dusts by handling infected materials and by drinking milk contaminated with *R burnetii* The disease in Australia is enzootic in animals especially bandicoots and is transmitted in nature by ticks Rickettsia laden tick feces may contaminate cattle hides and inhalation of such material has caused infection in man In the United States a number of species of ticks are naturally infected among them *Dermacentor andersoni* and *Amblyomma americanum* and in North Africa transovarial transmission of the agent in indigenous ticks has been demonstrated by Blanc Sheep goats and cows have been found naturally infected in Western United States and in Mediterranean areas and *R burnetii* has been recovered from the milk of such animals (Huebner et al 1948 Caminopetros 1948) Such milk as well as infected excretions from livestock probably accounts for certain

165 BRILL'S DISEASE (RECRUDESCENT TYPHUS)

T E Woodward and J E Smadel

Definition Brill s disease is a recrudescent episode of epidemic typhus fever which occurs years after the initial attack Nathan Brill in 1898 observed a sporadic disease which resembled typhus fever among nonlousy inhabitants of New York City Zinsser in 1934 suggested on the basis of epidemiologic and immunologic considerations that this malady was a recurrent form of typhus encountered in persons who had recovered from the epidemic disease while residing in countries where it was prevalent Additional information has gradually accumulated in support of this hypothesis and recently Murray and Snyder (1951) have been successful in regularly isolating rickettsiae indistinguishable from *Rickettsia prowazeki* in lice fed on patients during the active stages of illness

Clinical Manifestations The clinical entity not always mild resembles epidemic typhus fever as pertains to character of the rash circulatory disturbances hepatic renal and nervous system changes Recovery is the rule The Weil Felix reaction with the various *Proteus* antigens is usually negative or positive in very low titer in Brill s disease The specific complement fixation reaction is valuable in establishing the diagnosis The therapeutic procedures are comparable to those used in spotted fever which are described in detail on p 1028

166 SCRUB TYPHUS

T E Woodward and J E Smadel

Definition Scrub typhus is limited to eastern and southeastern Asia northern Australia and the adjacent islands It is caused by *Rickettsia tsutsugamushi* and characterized by a primary lesion at the site of the bite of an infected mite a fever of about 2 weeks duration a cutaneous rash which develops about the fifth day and the appearance late in the second week of agglutinins against the OX K strain of *Proteus* bacillus The broad spectrum antibiotics are specific therapeutic agents

Etiology The agent of scrub typhus resembles other rickettsiae in its physical properties but differs from them in antigenic structure vector and reservoir The disease is transmitted by larvae of several species of mites especially *Trombicula akamushi* and *T deliensis* These tiny chiggers attach themselves to the skin and during the process of obtaining a meal of tissue juice may acquire infection from the host or transmit rickettsiae to the vertebrate The infection is maintained in nature by a cycle involving mites and small rodents and by transovarial transmission in mites human infection represents an accident attributable to propinquity

Clinical Manifestations About 10 to 12 days after infection illness begins abruptly with chilliness severe headache fever conjunctival injection and moderate generalized lymphadenopathy which is most prominent in the nodes draining the area of the primary lesion The initial lesion at the beginning of fever is evidenced by an erythematous indurated area 1 cm in diameter surmounted by a multiloculated vesicle within a few days the vesicle ulcerates and becomes covered with a black crust

Fever increases progressively during the first week generally reaching 104 to 105 F but the pulse remains relatively slow i e 70 to 100 per min The red macular rash which begins on the trunk about the fifth day and spreads to the extremities sometimes becomes maculopapular but usually fades in a few days The course of the disease and the complications resemble those of endemic and epidemic typhus however interstitial myocarditis is more prominent than in the other typhus fevers

Prognosis Prior to the introduction of the broad spectrum antibiotics the mortality varied from 1 to 60 per cent depending on the geographic area and the virulence of the local strains of *R tsutsugamushi* and convalescence was prolonged With

Section 13 Viral Infections of the Respiratory Tract

168 COMMON RESPIRATORY DISEASE

A E Feller

The acute respiratory infections may be considered for purposes of discussion as a spectrum of clinical conditions with gradations in severity and extent from mild or minimal involvements of the respiratory passages to prostrating illnesses with or without pulmonary infiltration The group encompasses certain well known specific infections—i e influenza A influenza B beta hemolytic streptococcal infections and the bacterial pneumonias which are considered in other sections of this book But the greater part of the spectrum in terms of frequency of occurrence of cases is comprised of the large group of illnesses variously called the common cold coryza head cold nasopharyngitis laryngitis catarrhal fever flu grippe tracheitis bronchitis primary atypical pneumonia virus pneumonia etc The term *common respiratory disease* is employed in this section to refer collectively to this large and heterogeneous segment of the acute respiratory infections

The common respiratory diseases have not been satisfactorily classified A great deal of time and effort has been devoted to investigations of these infections but relatively little is yet known about their relationships and causation Clinical classification presents a difficult problem both in distinguishing illnesses of this group from those due to know viruses or bacteria and in separating the possible entities within the group

A group of viruses inhabiting the respiratory tract has been isolated in tissue cultures There has been confusion concerning terminology but a committee composed of interested investigators has now agreed upon the designation *adenoviruses* which will be employed hereafter Studies of the common respiratory diseases employing the adenoviruses have shed new light on the etiology epidemiology and clinical features of common respiratory disease However the results of investigations with the adenoviruses have not clarified the problem to the extent that common respiratory diseases can be discussed primarily from the etiologic point of view In civilian populations more than 90 per cent of respiratory illnesses are still of unknown or uncertain (though presumably viral) etiology

In this chapter emphasis is placed upon the general aspects of the problem but those illnesses or groups of illnesses which now appear to represent definite clinical entities are described It should be emphasized however that such segregation is mainly for convenience in describing the disease picture that the segments overlap one another and that many patients with common respiratory disease present manifestations which cannot be assigned clearly to any of the groups

History

Common respiratory disease has afflicted mankind for centuries Hippocrates (about 450 B C) and Galen and Celsus in the early Christian era described illnesses which almost certainly were respiratory infections possibly the common cold Since then many epidemics of respiratory disease have been described including influenza and others Difficulty of recognition of the various entities precludes specific interpretations in the history of common respiratory disease

Occurrence

The common respiratory diseases are world wide in distribution and no geographic area is known to be consistently free of them Certain isolated communities have been without respiratory illness for variable lengths of time but the resumption of intercourse with the outside world usually is followed by its reappearance Racial immunity or predisposition has not been established It is commonly believed that respiratory diseases are less prevalent in the warmer areas of the earth but there are insufficient data to determine whether the presumed difference is due to an actual decrease in attack rate to the occurrence of less severe illnesses to less crowding in the tropics or to incomplete observation

The respiratory diseases are highly prevalent in this country and are the most common cause of acute illness Data from industry show that they are among the leading causes of absenteeism from work Most persons have at least two or three acute respiratory infections each year

Epidemiology

The common respiratory diseases are distinctly seasonal and are confined largely to the cold months

outbreaks of human disease which appear attributable to inhalation of infected dust from barns and pens (Lennette and Welsh 1951) The method of spread of outbreaks of Q fever was not clearly established among stockyard workers in Texas and Illinois wool processers in Pennsylvania employees in a rendering plant in New York and laundry workers in Montana who hauled dirty linen from a laboratory engaged in studies in Q fever however the air borne route for dried contaminated material seems the most likely A number of epidemics have occurred among laboratory workers engaged in studies on *R burnetii* in various institutions throughout the world The disease is not transmitted from man to man

Clinical Manifestations After incubation of approximately 19 days (the range is 14 to 26) the *disease begins with headache chilly sensations* fever malaise myalgia and anorexia For several days the temperature ranges from 101 to 104 F the entire course may not exceed 2 weeks and usually ranges from 3 to 6 days There may be wide fluctuations of the fever Respiratory and gastrointestinal symptoms are not conspicuous in the early stages Headache and fever predominate A dry cough and chest pain occur after about 5 days when rales are usually audible Roentgenographic findings indistinguishable from those of primary atypical pneumonia are present usually by the third to fourth day of disease first as patchy areas of consolidation involving a portion of one lobe giving a homogeneous ground glass appearance These manifestations persist beyond the febrile period and may appear in patients who are unaware of pulmonary involvement Complications are rare and coincident with defervescence the appetite begins to return and convalescence progresses slowly for several weeks during which time the principal disability is weakness It is not uncommon for patients to lose 15 to 20 lb during the active stages of disease Several investigators have emphasized that the disease may be protracted in approximately 20 per cent of cases with fever persisting for longer than 4 weeks particularly in elderly patients Occasionally relapse occurs particularly in patients treated with antibiotics during the first several days of *disease Moreover hepatitis with the development* of clinically detectable icterus occurs in ap*proximately one third of patients* with the protracted form

Prognosis The prognosis from point of view of mortality is excellent and very few fatalities have been recorded in the modern literature Except for the patient with the protracted type of illness and hepatic involvement the course of disease is generally uncomplicated and benign

Treatment and Control Chlortetracycline oxytetracycline and chloramphenicol are effective in the treatment of patients with Q fever although the tetracycline antibiotics have been used more extensively Most patients when treated early in the course of disease respond promptly and recover without relapses The therapeutic procedures are comparable to those used in spotted fever which are discussed in detail on p 1028 It should *be emphasized that patients with hepatic involve*ment should receive careful attention to their dietary requirement particularly with relation to protein and carbohydrate intake Oxygen is beneficial in patients with severe interstitial pneumonitis

Etiology

Present Status of the Adenoviruses These agents have been variously called the AD APC or RI group of viruses but as noted in the introduction are now known as the adenoviruses The group is large but its members can be categorized on the basis of type specificity

The adenoviruses share certain common properties They have been propagated only in tissue cultures Overt disease in common laboratory animals has not been demonstrable All strains share a common complement fixing antigen At least 17 types can be distinguished by specific antibody neutralization Thus human infection by these viruses can be recognized serologically employing acute and convalescent phase serums Though less reliable for diagnosis than serologic methods isolation of the agents from respiratory secretions can be carried out The adenoviruses appear at present to be capable of producing at least two of the four types of common respiratory disease

Present data are insufficient to allow assignment of serotypes of the virus to particular clinical syndromes Available information clearly indicates that the adenoviruses are the cause of a variable and often large proportion of cases during epidemics of acute respiratory disease of army recruits especially types 4 and 7 and occasionally type 3 Some of these recruits with acute respiratory disease have had pulmonary infiltrates Type 3 virus has been found associated with respiratory disease in civilians especially with nonbacterial pharyngitis or "pharyngoconjunctival fever" Types 1 and 2 are present in civilian populations especially in the younger age groups but have not often been associated with clinical disease

COMMON COLD

Definition The common cold is an acute infection of the upper respiratory tract in which coryza is the prominent feature Constitutional symptoms are characteristically mild and there is little or no fever The acute symptoms usually last for only a few days

Etiology Transmission of the common cold to human volunteers and to chimpanzees using bacteria free filtrates of respiratory tract secretions indicates that the disease is caused by a virus The virus has not been isolated and characterized with certainty Adenoviruses with rare exceptions are absent from the respiratory secretions of patients with the common cold and antibodies to the known types of adenovirus do not increase in titer in convalescent phase serums of patients with naturally occurring colds or volunteers with induced colds

Manifestations The onset is gradual with a sensation variously described as irritation dryness rawness or tickling in the nasopharynx or the nose Frequently chilliness or malaise accompanies the local discomfort During the next 24 to 48 hr symptoms progress to those of the "full blown" cold (Fig 145) There are coryza sneezing nasal obstruction thin nasal discharge which may be profuse a feeling of tightness in the nose mouth breathing and watery eyes Malaise lassitude chilliness headache and the subjective feeling of feverishness with little or no change in body temperature add to general discomfort and irritability Patients may be described as not feeling well enough to work efficiently but not sufficiently ill to submit to bed rest During the next 2 or 3 days systemic symptoms gradually subside the nasal discharge becomes mucoid or purulent the coryza and nasal irritation become less troublesome and nasal obstruction lessens Thick discharge and some degree of nasal obstruction may persist for several days or even for weeks the frequency with which complicating paranasal sinusitis contributes to this picture is not certain

On physical examination the nasal mucosa is reddened and edematous and nasal discharge is usually obvious The nares may be reddened or excoriated and slight tenderness over the maxillary and frontal sinuses is frequent

No two individuals describe their colds in the same way The order in which the symptoms appear is variable the pharynx may be involved and the patient may develop a troublesome irritative cough finally productive of mucoid sputum

Laboratory Findings The leukocyte count differential leukocyte count and erythrocyte sedimentation rate are normal Cultures of the nasal secretion, nasopharynx or oropharynx usually reveal only the bacteria which are common inhabitants of these areas The urine is normal

Differential Diagnosis During the first 24 or 48 hr of illness it may be difficult to distinguish the common cold from the prodromal symptoms of the acute exanthems particularly measles Coryzal symptoms or signs in a young person should always lead to a search for Koplik spots and to inquiry about possible exposure

In the early stages of meningococcal infection the only symptoms may be coryza A purpuric rash headache or signs of meningeal irritation should be investigated in all patients with coryza particularly in young individuals

The most frequent problem is the separation of the common cold from other common respiratory infections especially the milder forms of acute undifferentiated respiratory disease

The sudden onset of sneezing itching in the nose and lacrimation characteristic pale boggy appearance of the turbinates and a history of

Table 96 TRANSMISSION OF COMMON RESPIRATORY DISEASE TO HUMAN VOLUNTEERS WITH BACTERIA FREE FILTRATES OF RESPIRATORY TRACT SECRETIONS

Donor of respiratory tract secretions clinical diagnosis	Results of inoculation in human volunteers	
	Incubation period	Character of illness produced in volunteers
Common cold	18–48 hr	Symptoms predominantly coryzal constitutional symptoms minor
Acute undifferentiated respiratory disease	4–7 days	Prominent symptoms pharyngeal constitutional symptoms present illnesses mild
Primary atypical pneumonia	12–14 days	Respiratory and constitutional symptoms pulmonary infiltration

of the year in the Temperate Zones Waves of increased prevalence occur in the fall winter and spring There is however a residue of these infections throughout the year in the population The thesis has been advanced that the minor illnesses tend to predominate in the fall or early winter and severe illnesses tend to be concentrated in the late winter and spring

Since recognition of the common respiratory diseases is dependent mainly upon clinical features epidemiologic concepts are applicable only to the problem as a whole Detailed epidemiologic data and the investigation of carriers or unapparent cases must await more definite information concerning the causation and interrelationships of the various illnesses Nevertheless certain concepts have become established and may be summarized as follows

1 The air borne route of transmission appears to be the most important but not necessarily the only mode of transfer

2 Certain studies particularly those of isolated communities suggest that carriers or very mild cases are capable of transmitting respiratory infections

3 Highest attack rates occur in children under the age of five years Infants under the age of one year have relatively low rates The lowest attack rates occur in the second decade of life The curve rises slowly to a small peak in the ages from twenty five to thirty five years and then gradually declines

4 In segregated populations such as military recruits or boarding school children a wave of respiratory infections may sweep through the population shortly after the individuals are brought together These outbreaks are followed by mass insusceptibility which can last for several months or possibly much longer In the military services *this phenomenon is* considered part of the "seasoning process The explanation for seasoning is unknown but aging and immunologic phenomena are probably important factors

5 Certain studies indicate that rigorous life or exposure to inclement weather *per se* are not important factors in provoking the occurrence of the common respiratory diseases

6 An increased prevalence of the common respiratory diseases contributes in some obscure manner to the increased occurrence of the bacterial pneumonias

CLASSIFICATION

Clinical classification of the common respiratory diseases presents a difficult problem because (1) the clinical picture in individual cases often does not differ from that of several specific diseases and (2) when studied in the mass the illnesses present smooth gradations in severity rather than sharp differences and there is a vast array of symptoms and physical signs which has not yet been reduced to relative simplicity An important reason for this difficulty of clinical classification is the limited manner in which the respiratory tract can respond to infection Influenza A is a good example because the diagnosis can be confirmed by laboratory methods When a population is studied during an *epidemic it is found that cases of influenza vary* greatly in severity and that many of the cases of proved influenza do not differ clinically from other respiratory infections occurring during the epidemic and demonstrated by laboratory methods not to be influenza

The most useful clinical classification employs as criteria the site of localization of the prominent symptoms or physical signs severity of illness the presence of exudate in the throat and the presence of pneumonia

CLASSIFICATION OF COMMON RESPIRATORY DISEASE

1 Common cold
2 Acute undifferentiated respiratory disease
3 Nonbacterial pharyngitis or tonsillitis
4 Primary atypical pneumonia

Limited support for the division into these clinical groups is given by etiologic studies carried out in human volunteers Transmission experiments employing bacteria free filtrates of respiratory tract secretions show that there are at least three agents presumably viruses which are capable of causing respiratory illness (Table 96)

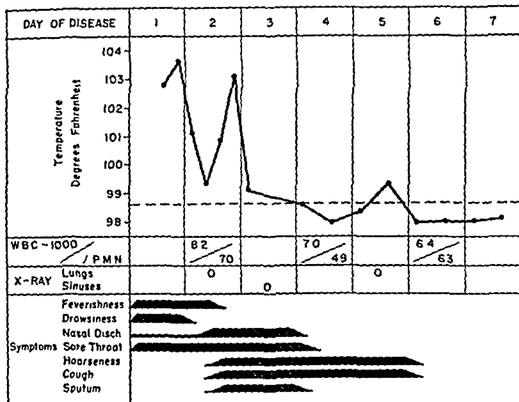

FIG. 146 Clinical chart of a patient with acute undifferentiated respiratory disease (*Commission on Acute Respiratory Diseases Fort Bragg N C J Clin Investigation* 26 959 1947)

lymphadenitis The lungs are usually clear but there may be tenderness or soreness to pressure over the sternum Pneumonitis occurs in a small proportion of cases

Acute undifferentiated respiratory disease is a more severe illness than the common cold (Fig 146) and many patients with the disease will seek or be willing to accept bed rest These patients are usually only moderately ill but occasionally may be prostrated Complete restoration of well being usually requires several days

Laboratory Findings The total and differential leukocyte counts are within normal limits although occasionally a count of 10 000 to 12,000 per cubic millimeter or even higher may be found The erythrocyte sedimentation rate is normal or only moderately increased Bacteriologic studies usually reveal only the organisms which are common residents of the respiratory tract.

In cases caused by adenoviruses the virus can be isolated from throat washings employing tissue cultures or a rise in titer of antibodies in paired acute and convalescent phase serums can be shown by complement fixation or neutralization techniques These procedures are not generally available and when employed have seldom been productive of positive results in civilian populations

Differential Diagnosis The differential diagnosis includes the common cold true influenza infectious mononucleosis primary atypical pneumonia the bacterial pneumonias and the acute exanthems in certain instances the problem becomes one of fever of unknown origin"

Influenza A and influenza B are difficult or impossible to differentiate from acute undifferentiated respiratory disease on clinical grounds although the constitutional symptoms in influenza tend to be more severe the onset may be more sudden and the conjunctivas may be injected During epidemics the diagnosis of influenza is not difficult but in the individual case the diagnosis can be made with certainty only on the basis of laboratory studies

Infectious mononucleosis should be suspected when there is enlargement of the lymph nodes in the posterior cervical triangles or elsewhere in addition to those in the anterior cervical triangles

The differentiation of *primary atypical pneumonia* from cases of acute undifferentiated respiratory disease with pneumonitis due to adenoviruses is possible only by laboratory methods

The *bacterial pneumonias* occasionally may be confused with acute undifferentiated respiratory disease during the first 12 or 24 hr of illness but the appearance of a pulmonary lesion, the more

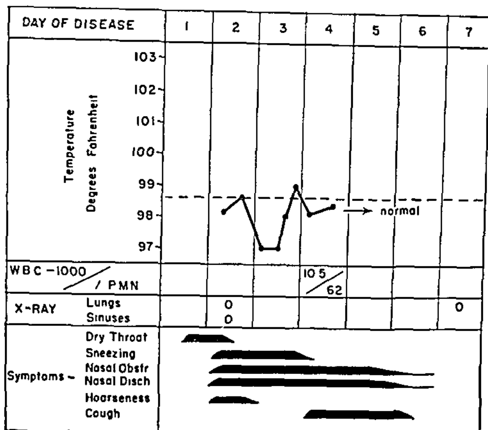

FIG 145 Clinical chart of a patient with a common cold (Commission on Acute Respiratory Diseases Fort Bragg N C J Clin Investigation 26 959 1947)

similar episodes are features which suggest allergic rhinitis rather than the common cold

ACUTE UNDIFFERENTIATED RESPIRATORY DISEASE

Definition Acute undifferentiated respiratory disease is an infection of the respiratory tract in which constitutional symptoms and fever are prominent Respiratory symptoms are likely to be localized to the throat trachea or bronchi and tend to be rather mild The illnesses in this group differ from the common cold in that they are more severe and systemic manifestations predominate over the local respiratory symptoms As employed here the term *acute undifferentiated respiratory disease* includes the *illnesses commonly called grippe or flu* but does not include influenza A or influenza B

Etiology It is not possible to delineate the etiology of acute undifferentiated respiratory disease at the present time In military recruit populations where the disease is particularly common and often occurs in epidemics the adenoviruses types 4 and 7 and to a lesser degree type 3 are the cause of many but not all such illnesses In some outbreaks only a small proportion of cases of clinically similar disease in recruits can be shown to be caused by these viruses In civilian populations several studies have revealed that type 4 and type 7 infections constitute a very small proportion of acute undifferentiated respiratory disease Thus while the discovery of the adenoviruses has not solved the over all problem of the etiology of this *group of illnesses it has clarified to some extent* the etiology of recruit illnesses

Manifestations The onset is gradual The prominent constitutional symptoms are feverishness chilliness and headache in addition malaise and anorexia are present in approximately 50 per cent of the patients The amount of fever varies widely but averages 101 F Sore throat with discomfort rather than actual pain on swallowing is the earliest and most salient respiratory symptom Hoarseness cough and discomfort in the chest described *as soreness or tightness are frequent* Nasal discharge and sneezing may occur but are usually minor The fever and malaise generally subside by the third day but *sore throat and hoarseness* often persist for a few days and it is not uncommon for the cough which may be productive of mucoid or purulent sputum to persist for one or more weeks

Physical signs are not characteristic The pharynx and fauces may be moderately reddened with prominent lymphoid follicles There is usually no pharyngeal exudate There is often mild cervical

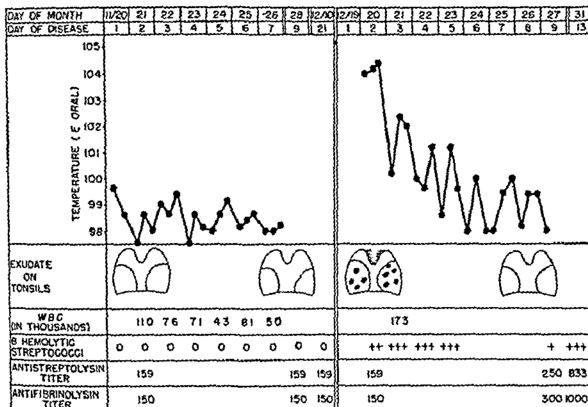

Fig 147 Clinical and laboratory data from a patient with nonstreptococcal exudative pharyngitis and tonsillitis of average severity (*left*) and from a patient with beta hemolytic streptococcal tonsillitis and pharyngitis (*right*) Note the absence of beta hemolytic streptococci in repeated throat cultures in the former and their presence in large numbers in the latter the rise in titer of antistreptolysin and antifibrinolysin (expressed in units) in convalescent phase serums in the latter the definite leukocytosis in the latter the differences in the amount of exudate on the tonsils and the presence of edema of the uvula and soft palate in the latter (*Commission on Acute Respiratory Diseases Fort Bragg N C J A M A* 133 588 1947)

infections have developed neither cold hemagglutinins nor agglutinins for streptococcus MG in their serums (2) Primary atypical pneumonia with cold hemagglutinins or streptococcus MG agglutinins or both This disease has been transmitted to human volunteers with bacteria free filtrates of sputum and throat washings and is presumed to be caused by a virus Isolation of the agent has not yet been clearly accomplished but such cases appear not to be caused by any of the known adenoviruses (3) Cases falling into neither of the above groups As yet the proportion of total cases which falls into each of these three groups is unknown Cases can be categorized only by laboratory studies

Manifestations The onset is insidious most patients have minor respiratory or constitutional symptoms for several days before consulting a physician Sudden onset is unusual

Early in the illness feverishness chilliness headache and malaise are the outstanding complaints Anorexia is common. Shaking chills are very unusual The headache is often frontal but may be occipital or generalized and is aggravated by cough the most common respiratory symptom The cough is frequently paroxysmal and harassing interfering with sleep It is nonproductive at first but mucoid or mucopurulent sputum is raised after a few days Streaks of bright red blood can appear in the sputum but grossly bloody rusty or "prune juice" sputum is very rare Substernal pain soreness or discomfort is common but pleural pain is very unusual The throat may be slightly sore dry or "scratchy"

Physical signs are not prominent especially early in the illness The patient appears mildly or moderately ill Fever rarely exceeds 104 F The pulse and respiratory rates are moderately increased Examination of the chest may reveal few signs in spite of the pulmonary lesions which are demonstrable radiographically Rales usually "sticky" in character may be heard over the involved area Early in the disease rales are audible only at the height

severe nature of the illness leukocytosis and identification of the causative agent soon clarify the picture

The disease may mimic the early symptoms and signs of the *acute exanthems* continued observation for characteristic signs of the latter disease is required

Occasionally acute undifferentiated respiratory disease may present only insignificant respiratory symptoms and brisk fever malaise anorexia and headache In such instances the appearance or intensification of respiratory symptoms may decide the issue but not infrequently the diagnosis is reached only after many other febrile disorders have been ruled out by continued observation and laboratory study Diagnosis by a process of exclusion is occasionally the only possible method

NONBACTERIAL PHARYNGITIS OR TONSILLITIS

Definition Nonbacterial pharyngitis or tonsillitis is an acute respiratory disease of unknown etiology in which exudate on the tonsils or pharynx is a distinctive feature In other respects it resembles acute undifferentiated respiratory disease rather closely but occasionally it presents symptoms and signs suggestive of beta hemolytic streptococcal tonsillitis or pharyngitis

Etiology The etiologic agent of this clinical entity is unknown in most instances The beta hemolytic streptococcus is excluded by definition Bacteriologic and limited serologic studies have indicated that other bacteria are not causative Adenovirus type 3 and occasionally other types have been found in several outbreaks of nonbacterial pharyngitis occurring principally in children in the summertime Some of these cases have had an associated conjunctivitis and Huebner and associates have employed the term *pharyngoconjunctival fever* for the condition Insufficient data are available to indicate what proportion of the total cases are caused by adenoviruses especially in adults

Manifestations Nonbacterial tonsillitis or pharyngitis is a mild disease of short duration (Fig 147 *left*) The onset is gradual as a rule The early symptoms in most cases are referable to the throat but fever or malaise is sometimes the presenting complaint The great majority of patients are febrile and develop malaise headache and anorexia During the acute illness the average maximum temperature is 101 to 102 F The febrile period is usually 2 or 3 days but may be longer

Sore throat is the most prominent respiratory symptom and is described as discomfort rawness or soreness rather than as actual pain or dysphagia Hoarseness cough and substernal discomfort are common There is a tendency for sore throat, hoarseness and especially cough to persist beyond the acute febrile period Sputum is scanty and usually mucoid

The chief physical signs are in the throat Exudate if present is white yellow or pearly gray and is located on the tonsils in the tonsillar fossae in the oropharynx or in all these areas The exudate is usually sparse and patchy The individual areas may be only pinhead in size but are frequently larger Confluent and extensive exudates are uncommon The pharynx is injected in the great majority of cases but the hyperemia is usually "streaky and only rarely is it diffuse or intense The lymphoid follicles of the pharyngeal wall are usually enlarged and reddened and frequently surmounted by small patches of exudate Edema of the soft palate or fauces is rarely prominent The lymph nodes in the anterior triangles of the neck are sometimes enlarged and tender Scattered rhonchi can be heard in about 15 per cent of cases

Laboratory Findings The total leukocyte count is usually normal but exceeds 10 000 per cubic millimeter in approximately one third of the cases The differential count is normal The erythrocyte sedimentation rate has not been adequately studied Throat cultures reveal normal flora By definition the illness is nonstreptococcal in origin and the predominance of beta hemolytic streptococci in a throat culture precludes the clinical diagnosis of nonstreptococcal exudative tonsillitis or pharyngitis

In cases caused by adenoviruses the agent has been isolated from throat washings Serologic techniques can be used to demonstrate a rise in titer of specific antibodies in paired acute and convalescent phase serums Thus far these techniques have yielded positive results more often in children than in adults but the data are not extensive

Differential Diagnosis (See p 852)

PRIMARY ATYPICAL PNEUMONIA

Definition Primary atypical pneumonia is an acute respiratory infection characterized by pulmonary lesions a paucity of physical findings in the chest constitutional symptoms cough sputum and prolonged convalescence

Etiology The etiology of primary atypical pneumonia has been a difficult problem since the condition was recognized almost two decades ago During this period several different viruses have been recovered from patients but none has been generally accepted as causally related to human disease Cases of primary atypical pneumonia can now be divided into at least three groups (1) Adenovirus infections many of which have pulmonary infiltrates and therefore are recognized as primary atypical pneumonias Patients with these

from those which occur with the common cold or acute undifferentiated respiratory disease groups

Complications of primary atypical pneumonia are unusual Pleural effusion is rare and when it occurs is almost invariably small bacteriologically sterile and readily absorbed Bacterial complications are rare Encephalitis meningoencephalitis or myocarditis occasionally occurs in severe cases and may lead to a fatal outcome Hemolytic anemia may occur during the acute illness Numerous other complications have been described but are exceedingly unusual

PATHOLOGY

The primary site of involvement in the common cold is the upper respiratory passages principally the nasal mucosa and frequently the lining membranes of the paranasal sinuses Histologically there are edema hyperemia and moderate infiltration with mononuclear cells and granulocytes Superficial necrosis and desquamation of epithelial cells ensues

The principal point of attack in acute undifferentiated respiratory disease appears to be the throat or the tracheobronchial tree rather than the nose The nature and degree of morphologic change are not known

The prominent morphologic changes in fatal cases of primary atypical pneumonia are necrotizing bronchitis and bronchiolitis and interstitial pneumonitis Multiple small endobronchial ulcerations covered with a thin grayish yellow membrane may be seen The pathologic changes are not distinctive and there are no features which distinguish them with certainty from other interstitial pneumonias Microscopic examination of the bronchi and bronchioles shows infiltration necrosis and ulceration of the walls The bronchioles are often dilated and pus epithelial cells cellular debris and mucus are present in the lumina In the pulmonary tissues surrounding the bronchi and bronchioles there are mononuclear infiltration and thickening of the alveolar septums Alveolar exudate is predominantly mononuclear Changes other than in the respiratory system are not commonly seen Acute myocarditis and hemorrhagic encephalitis have been described

PATHOGENESIS

The causative agents presumably viruses have an affinity for the mucous membrane of the respiratory tract Principal localization of the symptoms and signs to the nose in the common cold group to the pharynx in the acute undifferentiated respiratory disease and nonbacterial tonsillitis or pharyngitis groups and to the lung in the primary atypical pneumonia group suggests that the viruses of each group also possess an affinity for a particular area of the respiratory tract Limited support to the latter concept is given by the results of transmission experiments in human volunteers The widespread involvement of the respiratory tract which can occur in each of the four types of illness indicates however that the inflammatory process is more than a localized one

Data from transmission experiments employing the adenoviruses in human volunteers indicate varying success in the production of objectively recognizable illness when the inoculum is given intranasally Inoculations are usually successful however when the virus is applied to the conjunctiva As a rule human transmission experiments with the other common respiratory diseases have succeeded when the inoculum is applied to the upper respiratory passages (see Table 96) In the particular experiments noted in this table type 4 adenovirus appears to have been the agent of acute undifferentiated respiratory disease The possible natural transmission of common respiratory disease by way of the conjunctiva requires investigation

There is uncertainty concerning the role of bacteria in the pathogenesis of the common respiratory diseases but the weight of evidence indicates that bacteria are not primary incitants The chief points in favor of the hypothesis that bacteria commonly act as "secondary invaders are the facts that (1) there are reports that the total bacterial population increases as the inflammatory process proceeds especially when the secretions become thick and (2) certain specific organisms are present in large numbers in the secretions It is difficult to interpret these observations The unconvincing nature of this evidence however does not justify the categorical statement that bacteria do not act as secondary invaders in the common respiratory diseases

Evidence that "allergy" or "bacterial allergy is an important factor in the pathogenesis of common respiratory disease is neither substantial nor convincing

IMMUNITY

The isolation identification and characterization of the agents of common respiratory disease must be accomplished before an attempt can be made to evaluate the role of the parasite in the immune mechanism Repeated or successive respiratory infections in an individual do not necessarily imply lack of immunity unless it can be established that a single agent is responsible Further consideration of the role of the parasite seems fruitless until more of the agents are identified

Information concerning immunity in the host is

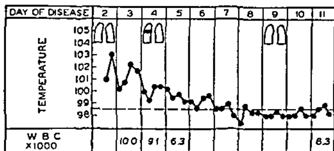

Fig 148 Clinical chart of a patient with primary atypical pneumonia of moderate severity (*Dingle et al War Medicine* 3 223 1943)

of inspiration although later in the illness rales and rhonchi are often widespread Other signs of consolidation are rarely prominent

Roentgenographic examination of the chest is the most reliable method of detecting the pulmonary lesions The pulmonary infiltrates are typically soft diffuse patchy or nodular and poorly outlined The earliest lesions often begin as a hilar enlargement which then fans out The lower lobes are most frequently involved but multilobar disease is common The lesions vary from slight stringy peribronchial shadows to extensive infiltration that is indistinguishable from that of pneumococcal pneumonia One to three weeks is usually required for resolution

The course of illness is variable In the usual case (Fig 148) fever and acute illness last 5 to 8 days Very mild illness or asymptomatic infection recognized only by roentgenograms occurs Severe illnesses are also encountered in such cases patients may be critically ill cyanotic and dyspneic

Convalescence is typically prolonged There is continued cough and return of strength and well being is slow Complete recovery without residual disability is the rule

Laboratory Findings The laboratory findings in the average case of primary atypical pneumonia are usually within normal limits *The total leukocyte count* differential formula and urine are normal Leukocytosis of 20 000 per cubic millimeter or higher can occur after the first week Early leukocytosis should suggest some other disease The erythrocyte sedimentation rate may be increased but this is not consistent Serum chloride and amino acid levels are not altered as in pneumococcal pneumonia

The appearance of cold hemagglutinins for human group O erythrocytes or of agglutinins for streptococcus MG in the blood are of value in the *retrospective diagnosis of primary atypical pneumonia* These agglutinins do not increase in titer until the second or third week after onset and are therefore not useful at the time therapeutic considerations are paramount Cold hemagglutinins are *demonstrable in approximately 50 per cent of cases* The incidence of cold hemagglutinins is increased in the more severe illnesses as judged by the height and duration of fever and the number of lobes of the lung which are involved Agglutinins for streptococcus MG are present in approximately 25 per cent of cases but the incidence increases with the *severity of illness The absence of cold hemagglutinins or agglutinins for streptococcus MG or both* does not of course exclude the diagnosis of primary atypical pneumonia

As noted above certain cases may be due to the adenoviruses particularly in military recruits and in such cases cold hemagglutinins and agglutinins for streptococcus MG have been absent

False positive Wassermann reactions occur in primary atypical pneumonia The occurrence of several other serologic reactions in convalescent phase serums indicates that serologic tests in general should be interpreted with caution in this disease

Differential Diagnosis (See p 835)

COMPLICATIONS OF COMMON *RESPIRATORY DISEASE*

Purulent paranasal sinusitis otitis media mastoiditis and bacterial pneumonia are frequent and often serious complications of the common respiratory diseases These conditions are true bacterial infections Pneumococci staphylococci and streptococci are the chief offenders Secondary bacterial infection should be suspected if fever increases or leukocytosis occurs

Several other conditions are often considered to be complications of common respiratory disease Copious thick nasal exudate postnasal discharge laryngitis hoarseness aphonia and chronic cough productive of mucoid or mucopurulent sputum occur so frequently either during the acute illness *or as the acute process begins to subside* that they may well be an integral part of the clinical picture Painful involvement of the paranasal sinuses during the acute illness seems in many instances properly to be regarded as an extension of the original inflammatory process There is much uncertainty about a role of bacteria as "secondary invaders" in these conditions

Herpes of the lips or face is particularly frequent in the common cold group However in primary atypical pneumonia herpes is so unusual that its presence strongly suggests a bacterial etiology of pneumonia

Relatively little is known about the complications in nonbacterial tonsillitis or pharyngitis There is as yet no indication that they differ appreciably

169 INFLUENZA

Robert R Wagner

Definition Influenza is an acute respiratory infection of specific viral etiology characterized by sudden onset of headache myalgia fever and prostration The terms *influenza* and flu" should not be loosely applied to all common respiratory diseases with systemic manifestations but should be restricted to those cases with clear-cut epidemiologic or laboratory evidence of infection with influenza viruses

History Influenza is an Italian word meaning influence" (originally referring to the influence of the stars) which first came into common English usage during the European epidemic of 1743 According to the best available records the disease was uncommon in Europe during the nineteenth century until the pandemic of 1889 Subsequently the frequency and severity of epidemics increased culminating in the disastrous pandemic of 1918 which caused an estimated 20 to 40 million deaths From 1920 until the present there has been a gradual but inconstant decline in the incidence and severity of the disease The isolation of the causative organism in 1933 by Smith Andrewes and Laidlaw led to the development of simple diagnostic

still far from complete It is commonly believed that there is little or no immunity to the common cold One s personal experience of having repeated attacks of the disease often serves to confirm this conviction Furthermore experiments with human volunteers show that challenge reinoculation with common cold filtrates in the early postconvalescent period may induce a second illness Immunity to the common cold may occur but is not a solid or lasting immunity

Epidemiologic studies indicate that immunity to acute undifferentiated respiratory disease develops in army recruits following the wave of illness occurring shortly after they are brought together as a military organization How widely this principle may be applied to the acute undifferentiated respiratory disease group as a whole is an unsolved problem

Host immunity in nonbacterial tonsillitis or pharyngitis has been essentially unexplored However studies with type 3 adenovirus in volunteers have shown that type specific antibody either vaccine induced or naturally acquired affords a definite degree of protection from illness when volunteers are challenged by inoculation of the virus onto the conjunctiva

Numerous reports indicate that second attacks of primary atypical pneumonia occur even though only a few weeks or months have elapsed since the first attack Evaluation of these data is not possible because information concerning the number of agents which may cause primary atypical pneumonia is lacking

The existence of local immunity in the respiratory tract has been suggested but not proved

PREVENTION

As noted in the section on immunity studies with type 3 adenovirus vaccines have shown that a definite degree of protection against illness from challenge inoculation of the virus onto the conjunctiva is induced by the vaccine Adenovirus vaccines containing types 3 4 and 7 virus have given promising results in military recruit populations

Except for the adenovirus vaccines just noted there are no established methods procedures or immunizing agents effective for preventing common respiratory disease Various "cold vaccines" or "cold shots" are widely employed but none has as yet been shown to be of prophylactic value when tested in controlled experiments

Adequate rest a nutritious diet sensible avoidance of undue exposure to cold or wet and avoidance of exposure to those with respiratory infections seem reasonable and advisable but cannot be relied upon to prevent the common respiratory diseases

PROGNOSIS

In the absence of complications the prognosis for life is uniformly good although primary atypical pneumonia in the debilitated or in patients with chronic disease—e g cardiac disease asthma etc —may be serious or fatal Fatalities in young adults occur in approximately one in a thousand cases of primary atypical pneumonia the fatality rate in children and the aged is not established but is probably higher

TREATMENT

There is no specific treatment for common respiratory disease the sulfonamides and antibiotics at present available are not of value for the treatment of the primary illness

Symptomatic therapy is often overdone Aspirin is as good as any of the various compounds employed for the relief of feverishness headache and malaise The "antihistaminic" drugs are of little value for the treatment of the common cold or other common respiratory diseases Any of several cough sirups particularly those containing codeine are useful for the control of cough

Routine use of the sulfonamides or antibiotics for the prophylaxis of the bacterial secondary invaders is to be condemned Their use in therapeutic doses is justified when the bacterial complications are present

Patients with severe primary atypical pneumonia may be dyspneic or cyanotic the use of oxygen is very helpful and occasionally it appears to be life saving In general bed rest for a few days after the temperature is normal is advisable but resolution of the pulmonary process does not appear to be necessary before ambulation

Several reports suggest that the tetracycline drugs are of value in the treatment of primary atypical pneumonia although there is now general agreement that the sulfonamides and penicillin are ineffective Chlortetracycline appears to have been of striking benefit in many cases but in others little or no effect has been obtained It is difficult to interpret these results because the course of the disease is unpredictable Thus no definitive recommendation as to the use of the broad spectrum antibiotics in primary atypical pneumonia can be made at present

Badger G F J H Dingle A F Feller R G Hodges W S Jordan and C H Rammelkamp A Study of Illness in a Group of Cleveland Families II Incidence of the Common Respiratory Diseases Am J Hyg 58 31 1953

the lumbosacral area occurs in more than half the cases this is often so severe that the patient is reluctant to move Pain and spasm localized to the abdominal muscles may simulate acute peritonitis and incapacitating periarticular pains are sometimes confused with acute arthritis Some observers have commented on the frequency of faintness and dizziness as early symptoms *Feverishness* and *chilliness* or occasionally true rigors may be the first manifestations but more often they are preceded by headache and myalgia The temperature rises abruptly to a maximum of 100 to 103 F several hours after onset rarely it may reach 106 F Thereafter the fever and pain usually subside over a 2 to 3-day period but can persist for as long as a week A common variant in the temperature course is rapid defervescence after the initial peak, with a secondary rise to the original level on the following day In general severity of illness parallels the height and duration of the fever The pulse rate is usually slow in relation to the fever but marked tachycardia can occur in severely ill patients

Prostration of some degree is almost invariable and is often the most prominent and alarming manifestation The face is usually flushed and the skin hot and dry however profuse sweating and cold mottled extremities are sometimes noted A peculiar type of "heliotrope facial cyanosis occurred during the 1918 pandemic but it is rarely seen at present Anorexia nausea and constipation are frequent secondary symptoms but vomiting and diarrhea are rare There is no evidence that influenza viruses infect the gastrointestinal tract, and the term *intestinal flu* is a misnomer Meningoencephalitis polyneuritis cranial nerve palsies transient nerve deafness aphasia hemiplegia, and other neurologic disorders have been described in association with influenza but are very unusual Hypotension heart block, and fatal myocarditis have also been reported in a few cases. The exact relationship of these neurologic and cardiovascular disorders to influenza viral infection has not been determined

Respiratory symptoms may be present at the onset but become most prominent when the systemic manifestations and fever begin to subside They are frequently less pronounced than in common respiratory disease and can be entirely absent Sneezing watery nasal discharge or stuffy nose occurs in most cases hoarseness and epistaxis are less frequent Conjunctival suffusion and burning itching watery eyes are often noted Sore throat is not a usual complaint although the throat may feel dry and the pharynx often appears slightly injected *Cough* develops during the course of the illness in more than three fourths of the cases and in about a third of these it is productive of small amounts of tenacious mucoid sputum *Chest pain* usually substernal in location and accentuated by coughing but not by breathing is present in almost half the patients Pleurisy and pleural effusion are uncommon Slight hyperpnea is often noted but the most ominous although infrequent signs are dyspnea and cyanosis which signal bronchiolar or pneumonic involvement Physical examination of the *lungs is often negative in uncomplicated influenza,* but scattered rhonchi wheezes and showers of moist rales have been reported in 5 to 40 per cent of cases in different epidemics Influenzal bronchiolitis should be suspected if rales persist in the absence of x ray evidence of pneumonitis and if the patient raises mucopurulent or blood tinged sputum

The chief *complications* of influenza are secondary bacterial infections of the paranasal sinuses middle ear bronchi and lungs The incidence of bacterial pneumonia is greatly increased during influenza epidemics even mild or asymptomatic infections with influenza viruses predispose to pneumococcal and other types of pneumonia The most serious complication in recent years has been staphylococcal pneumonia, which tends to run a fulminant often fatal course Superinfection with *Hemophilus influenzae* so common in the pandemic of 1918 is rarely encountered now

Recovery from uncomplicated influenza is often complete in 2 to 3 days or occasionally in a week but convalescence may be prolonged by "postinfectious asthenia" and depression, particularly in elderly people Minor relapses with fever can occur but are uncommon

Laboratory Findings Virus can be isolated during the acute phase of the disease by inoculation of nasopharyngeal secretions or broth garglings into the amniotic cavity of chick embryos A minimum period of 5 days is required to identify the virus Serologic diagnosis can be made by hemagglutination inhibition or complement fixation tests only if serum samples are obtained in both the acute and convalescent phases

X ray of the lungs in uncomplicated influenza is usually normal but occasionally reveals increased vascular markings basilar streaking small areas of patchy infiltration, atelectasis nodular densities or pleural effusion The blood leukocyte count can be low normal, or slightly elevated Leukocytosis above 15 000 indicates secondary bacterial infection but it is well to remember that leukopenia can occur in severe staphylococcal pneumonia Slight proteinuria is common during the febrile illness

Differential Diagnosis Many bacterial and viral infections simulate influenza at their onset, but few febrile diseases have such a self limited course The pattern of clinical manifestations becomes readily

tests which have greatly advanced knowledge of the clinical variations epidemiology and pathogenesis of the disease

Etiology There are at present three known antigenic types of influenza virus designated A B and C in the order in which they were discovered Infection with one type confers no immunity against the other two They are all approximately 100 mμ in diameter visible as spheres or filaments by electron microscopy and are biologically related by their infectivity for chick embryos capacity to agglutinate erythrocytes and affinity for the respiratory epithelium of various mammals Influenza viruses are the prototypes of the myxovirus group which also includes mumps Newcastle disease fowl plague Japanese newborn pneumonitis (Sendai) and croup viruses

Epidemiology Influenza B and C usually occur sporadically or in localized outbreaks particularly in schools and military camps Influenza A viruses are the cause of major epidemics which tend to recur in the winter months at intervals of 2 to 4 years The factors responsible for this epidemic periodicity are the decline in effective immunity of a population in interepidemic periods and the emergence every few years of new strains of virus *slightly different antigenically from the former* strains A marked change in the antigenicity of type A viruses occurred in 1946–1947 when viruses extant between 1933 and 1945 completely disappeared and were replaced by strains designated as influenza A

A further more pronounced alteration in the serotype of influenza A viruses was detected in China early in 1957 These Asian" influenza strains were widely disseminated in the Orient in the following spring and subsequently throughout the world giving rise to the Asian influenza pandemic of 1957 Certain epidemiologic and immunologic features of "Asian" influenza resemble the pandemic of 1889

Influenza A epidemics start abruptly reach a peak in 2 to 3 weeks and subside almost as rapidly The attack rate is extremely variable but at times may exceed 40 per cent of urban populations The enigma of epidemic influenza has been that outbreaks caused by the same strain of virus often appear simultaneously in widely separated areas The most likely explanation of this epidemiologic paradox is that relatively avirulent virus which causes minor or asymptomatic respiratory infections is widely seeded during the summer months It then remains dormant until external factors such as cold and inclement weather precipitate outbreaks at many foci Thereafter rapid spread of infection in susceptible individuals apparently results in increased virulence of the virus

Pathogenesis Fatal influenza uncomplicated by bacterial infection is rare at present therefore most of the information on pathogenesis comes from studies of laboratory animals *particularly ferrets* and mice After intranasal inoculation the virus multiplies to maximum levels in 24 to 48 hr and rapidly involves the entire tracheobronchial tree At first the mucosa becomes boggy and hyperemic and loses its normal ciliary activity This is shortly followed by necrosis of respiratory epithelium invasion by leukocytes pulmonary consolidation, and abnormal regeneration of metaplastic squamous epithelium The infection is confined to the respiratory tract and hilar lymph nodes of adult animals viremia is a transient and inconstant feature

Similar lesions are found in the bronchi and lungs of fatal human cases but it is not known whether they are caused by the virus itself or by secondary bacterial invaders The most frequent findings at autopsy during the 1918 pandemic were pulmonary hemorrhages necrosis of bronchial epithelium bronchiolitis squamous metaplasia of respiratory epithelium hyaline membrane formation and marked edema of alveolar walls and spaces

Manifestations The clinical features and severity of the disease vary with the age and general health of the individual Infants generally have *a benign* course with little fever whereas incapacitating or even fatal infections can occur in elderly patients particularly those with preexisting pulmonary or cardiac disease The high mortality rate in young adults that characterized the pandemic of 1918 fortunately has not recurred The disease assumes its most typical form during major epidemics of influenza A but clinical differentiation between influenza A and B is not possible in localized outbreaks Sporadic infections with either influenza A or B are likely to result in relatively minor illnesses with predominantly respiratory symptoms similar to those of common respiratory disease (see p 1042) Influenza C is particularly difficult to recognize because of its mildness Although the manifestations and severity of influenza A vary from year to year cases in a single epidemic often follow a remarkably similar pattern The clinical description that follows is a composite picture of epidemic influenza A of the past decade

The incubation period is usually 18 to 36 hr but may be as long as 3 days Mild prodromal symptoms of cough malaise and chilliness are sometimes present but extremely sudden onset is often such a characteristic feature that many patients can recall its exact time The most common initial symptom is severe generalized or frontal *headache* frequently accompanied by stabbing retroorbital pain that is accentuated by lateral or upward gaze Diffuse *myalgia* particularly marked in the legs and over

the lumbosacral area occurs in more than half the cases this is often so severe that the patient is reluctant to move Pain and spasm localized to the abdominal muscles may simulate acute peritonitis and incapacitating periarticular pains are sometimes confused with acute arthritis Some observers have commented on the frequency of faintness and dizziness as early symptoms *Feverishness* and *chilliness or occasionally true rigors may be the first* manifestations but more often they are preceded by headache and myalgia The temperature rises abruptly to a maximum of 100 to 103 F several hours after onset rarely it may reach 106 F Thereafter the fever and pain usually subside over a 2 to 3 day period but can persist for as long as a week A common variant in the temperature course is rapid defervescence after the initial peak with a secondary rise to the original level on the following day In general severity of illness parallels the height and duration of the fever The pulse rate is usually slow in relation to the fever but marked tachycardia can occur in severely ill patients

Prostration of some degree is almost invariable and is often the most prominent and alarming manifestation The face is usually flushed and the skin hot and dry however profuse sweating and cold mottled extremities are sometimes noted A peculiar type of "heliotrope" facial cyanosis occurred during the 1918 pandemic but it is rarely seen at present Anorexia nausea and constipation are frequent secondary symptoms but vomiting and diarrhea are rare There is no evidence that influenza viruses infect the gastrointestinal tract and the term *intestinal flu* is a misnomer Meningoencephalitis polyneuritis cranial nerve palsies transient nerve deafness aphasia hemiplegia and other neurologic disorders have been described in association with influenza but are very unusual Hypotension heart block and fatal myocarditis have also been reported in a few cases The exact relationship of these neurologic and cardiovascular disorders to influenza viral infection has not been determined

Respiratory symptoms may be present at the onset but become most prominent when the systemic manifestations and fever begin to subside They are frequently less pronounced than in common respiratory disease and can be entirely absent Sneezing watery nasal discharge or stuffy nose occurs in most cases hoarseness and epistaxis are less frequent Conjunctival suffusion and burning itching watery eyes are often noted Sore throat is not a usual complaint although the throat may feel dry and the pharynx often appears slightly injected *Cough* develops during the course of the illness in more than three fourths of the cases and in about a third of these it is productive of small amounts of tenacious mucoid sputum *Chest pain* usually substernal in location and accentuated by coughing but not by breathing is present in almost half the patients Pleurisy and pleural effusion are uncommon Slight hyperpnea is often noted but the most ominous although infrequent signs are dyspnea and cyanosis which signal bronchiolar or pneumonic involvement Physical examination of the *lungs is often negative in uncomplicated influenza* but scattered rhonchi wheezes and showers of moist rales have been reported in 5 to 40 per cent of cases in different epidemics Influenzal bronchiolitis should be suspected if rales persist in the absence of x ray evidence of pneumonitis and if the patient raises mucopurulent or blood tinged sputum

The chief *complications* of influenza are secondary bacterial infections of the paranasal sinuses middle ear bronchi and lungs The incidence of bacterial pneumonia is greatly increased during influenza epidemics even mild or asymptomatic infections with influenza viruses predispose to pneumococcal and other types of pneumonia The most serious complication in recent years has been staphylococcal pneumonia which tends to run a fulminant often fatal course Superinfection with *Hemophilus influenzae* so common in the pandemic of 1918 is rarely encountered now

Recovery from uncomplicated influenza is often complete in 2 to 3 days or occasionally in a week but convalescence may be prolonged by "postinfectious asthenia" and depression particularly in elderly people Minor relapses with fever can occur but are uncommon

Laboratory Findings Virus can be isolated during the acute phase of the disease by inoculation of nasopharyngeal secretions or broth garglings into the amniotic cavity of chick embryos A minimum period of 5 days is required to identify the virus Serologic diagnosis can be made by hemagglutination inhibition or complement fixation tests only if serum samples are obtained in both the acute and convalescent phases

X ray of the lungs in uncomplicated influenza is usually normal but occasionally reveals increased vascular markings basilar streaking small areas of patchy infiltration atelectasis nodular densities or pleural effusion The blood leukocyte count can be low normal or slightly elevated Leukocytosis above 15 000 indicates secondary bacterial infection but it is well to remember that leukopenia can occur in severe staphylococcal pneumonia Slight proteinuria is common during the febrile illness

Differential Diagnosis Many bacterial and viral infections simulate influenza at their onset, but few febrile diseases have such a self limited course The pattern of clinical manifestations becomes readily

apparent during an epidemic but many influenza outbreaks are associated with an increased incidence of other respiratory infections of viral and bacterial etiology Noninfluenzal respiratory diseases (see p 1042) are generally characterized by more gradual onset milder systemic manifestations and predominant symptoms of coryza rhinorrhea pharyngitis and conjunctivitis

Treatment Antibiotics do not affect the course of uncomplicated influenza nor is there any evidence that they prevent complications Specific chemotherapy should be reserved for secondary bacterial infections Codeine affords relief from incapacitating cough and is more effective than salicylates for symptomatic treatment of headache and myalgia salicylates often increase discomfort by causing drenching sweats and chills Bed rest and gradual return to full activity are advisable to prevent prolonged postinfectious asthenia

Prophylaxis Formalinized egg vaccines containing a mixture of influenza A and B viruses are available for subcutaneous or intradermal vaccination Although they stimulate the production of serum antibodies their value in influenza prophylaxis is limited by the following factors (1) infection can occur in spite of high levels of serum antibody (2) antibody concentration is low at the site of infection in the respiratory tract (3) vaccines are usually prepared from viruses that differ antigenically from the most recent strains and (4) even under optimal conditions their protective effect lasts only a few months Nevertheless there is ample evidence that the vaccines presently available reduce the incidence of influenza *during epidemics* in closed population groups (boarding schools and military camps) although their effectiveness in the general population is open to question The vaccines are not innocuous Fatal anaphylactic reactions have been reported in individuals sensitive to egg proteins and killed virus itself is pyrogenic and can produce an illness similar to active influenza Vaccine should never be administered to infants or young children in whom severe febrile reactions may result in convulsions and death

170 PSITTACOSIS

Robert R Wagner and Ivan L Bennett Jr

Definition Psittacosis is an infectious disease of birds caused by a large virus Transmission of the virus from birds to man results in a febrile illness characterized by pneumonitis and systemic manifestations The name *ornithosis* is sometimes applied to infections contracted from birds other than parrots or parakeets but *psittacosis* is the more common and preferred term for all forms of the disease

History In 1880 a Swiss physician Ritter reported a fatal pneumonic illness in patients who had been in contact with sick birds Psittacosis was considered to be a rare and exotic disease until 1929 to 1930 when almost 800 cases occurred in Europe Asia and America This "pandemic" was traced to a shipment of South American parrots (Meyer 1942) Psittacosis is now a reportable disease in most states and at least 1 000 cases a year occur in the United States alone

Etiology The causative organism is an obligate intracellular parasite which is usually referred to as a virus although it more nearly resembles a rickettsia in size staining properties and susceptibility to antibiotics It is closely related to the virus of lymphogranuloma venereum and to a variety of animal viruses which have not been shown conclusively to produce human disease Psittacosis is widely distributed throughout the world and almost any avian species can harbor the virus Psittacine birds are most commonly infected but human cases have been traced to contact with pigeons ducks turkeys chickens and other birds Psittacosis can be considered an occupational disease of pet shop owners poultry raisers pigeon fanciers taxidermists and zoo attendants The incidence of human infection has steadily risen during the past decade owing in large part to the increasing popularity of parakeets and related birds as pets and the easing of regulations banning their importation and interstate shipment

Psittacosis is almost always transmitted to man by the respiratory route On rare occasions the disease may have been acquired from the bite of a pet bird The virus is present in nasal secretions excreta tissues and feathers of infected birds Although the disease can be fatal infected birds fre

quently show only minor evidences of illness such as ruffled feathers lethargy and anorexia Asymptomatic carriers are common and complete recovery can be followed by continued shedding of virus for many months Oral administration of antibiotics does not eradicate the infection in parrots and parakeets Intimate and prolonged contact is not *essential for transmission of the disease to man* a few minutes spent in an environment previously occupied by an infected bird has resulted in human infection The severity of the disease in man bears no apparent relationship to closeness or duration of contact Human to human transmission of psittacosis has occurred particularly among hospital personnel and the resulting infections are unusually severe often fatal There is evidence that these "human" strains differ slightly from native avian viruses There is no record of infection acquired by eating poultry products

Pathogenesis Psittacosis virus gains entrance to the body through the upper respiratory tract and eventually localizes in the pulmonary alveoli and the reticuloendothelial cells of the spleen and liver Invasion of the lung parenchyma probably takes place by way of the blood stream rather than by direct extension from the upper air passages A lymphocytic inflammatory response occurs on both the interstitial and respiratory surfaces of the alveoli as well as in the perivascular spaces The alveolar walls and interstitial tissues of the lung are thickened edematous necrotic and occasionally hemorrhagic Histologically the affected areas show alveolar spaces filled with fluid erythrocytes and lymphocytes The picture is not pathognomonic of psittacosis unless macrophages containing characteristic cytoplasmic inclusion bodies (L C L bodies) can be identified The respiratory epithelium of the bronchi and bronchioles is usually intact

Manifestations The clinical manifestations and course of psittacosis are extremely variable After an incubation period of 7 to 14 days the disease may start abruptly with shaking chills and high fever but the onset is more often gradual with increasing fever and malaise over a 3 to 4 day period Headache is almost always a prominent symptom it is usually diffuse and excruciating and often the patient's chief complaint Generalized myalgia is also common Spasm and stiffness of the muscles of the back and neck can lead to an erroneous diagnosis of meningitis A faint macular rash (*Horder's spots*) simulating the rose spots of typhoid fever has been described Delirium and stupor occur near the end of the first week in severe cases but other neurologic manifestations are extremely rare Occasional patients are *comatose when first seen* by a physician and the diagnosis of psittacosis may be missed in this circumstance Gastrointestinal complaints [illegible] pain nausea vomiting or diarrhea are present in some cases constipation and abdominal distention sometimes occur as late complications Icterus the result of severe hepatic involvement is a rare and ominous finding Symptoms of upper respiratory infection are not prominent although mild sore throat pharyngeal injection and cervical adenopathy are often present *Epistaxis is encountered early in the course of* nearly one fourth of the cases

The dry hacking cough of atypical pneumonia is characteristic of psittacosis it is usually nonproductive but small amounts of mucoid or bloody sputum may be raised as the disease progresses Cough may appear early in the course of the disease or as late as 5 days after the onset of fever Chest pain pleurisy with effusion or a friction rub can all occur but are not usual Pericarditis and myocarditis have been reported Most patients have a normal or slightly increased *respiratory rate* marked dyspnea with cyanosis occurs only in severe psittacosis with extensive pulmonary involvement In psittacosis as in most nonbacterial pneumonias the physical signs of pneumonitis tend to be less prominent than symptoms and x ray findings would suggest The initial examination may reveal fine sibilant rales on auscultation of the chest or clinical evidence of pneumonia may be completely lacking Rales usually become audible and more numerous as the illness progresses Signs of frank pulmonary consolidation are usually absent Patients without cough or other clinical evidence of respiratory involvement present the problem of a *fever of unknown origin* The pulse rate in psittacosis is slow in relation to the fever Splenomegaly when present in a patient with acute pneumonitis strongly suggests psittacosis Inability to feel the spleen is of no diagnostic significance however the *reported incidence* of splenomegaly has ranged from 10 to 70 per cent in different *series of proved cases* It should be remembered that the spleen is only slightly enlarged and is more frequently palpable late in the course of the disease Nontender hepatic enlargement also occurs but jaundice is rare Thrombophlebitis is not unusual during *convalescence in*deed pulmonary infarction is a common late complication and *may* be fatal

In untreated cases of psittacosis sustained or mildly remittent fever persists for 10 days to 3 weeks Defervescence is by lysis *rarely by crisis* and is accompanied by abatement of respiratory manifestations Psittacosis contracted from parrots or parakeets is more likely to be a *severe* prolonged illness than infections acquired from pigeons or barnyard fowl Relapses occur but are rare *Secondary* bacterial infections are *uncommon* Immunity to reinfection is probably *permanent*

Laboratory Findings The x ray of the lungs in psittacosis mimics a great *variety* of pulmonary dis

eases The pneumonic lesions are usually patchy in appearance but can be hazy diffuse homogeneous lobar atelectatic wedge shaped nodular or miliary The white blood cell count is normal or moderately decreased in the acute phase of the disease but may rise in convalescence The erythrocyte sedimentation rate is frequently not elevated Transient proteinuria is common The cerebrospinal fluid sometimes contains a few mononuclear cells but is otherwise normal Cold agglutinins are rarely present in the serum of patients with psittacosis

The diagnosis of psittacosis can be confirmed only by virus isolation or serologic studies The virus is present in the blood during the acute phase of the disease and in the bronchial secretions for weeks or sometimes years after infection but it is often difficult to isolate Psittacosis is most readily diagnosed by the demonstration of a rising titer of complement fixing antibody in the patient s blood An acute and convalescent specimen should always be tested Even a low titer of antibody during the acute febrile phase constitutes presumptive evidence of psittacosis The prompt initiation of treatment with tetracycline has been shown to delay antibody rise in convalescence for several weeks or months Interpretation of a single complement fixation test can sometimes be difficult because of the antigenic cross reaction between the viruses of psittacosis and lymphogranuloma venereum

Differential Diagnosis A history of exposure to birds may be the only clinical basis for differentiating psittacosis from a great variety of infectious and noninfectious febrile disorders A partial list of pneumonic diseases that can be confused with psittacosis includes primary atypical pneumonia, Q fever coccidioidomycosis tuberculosis carcinoma of the lung with bronchial obstruction and bacterial pneumonias In the early stages before pneumonitis appears psittacosis can be mistaken for influenza, typhoid fever miliary tuberculosis brucellosis infectious mononucleosis and less commonly rheumatic fever or bacterial endocarditis

Treatment The tetracyclines are consistently effective in the treatment of psittacosis Defervescence and alleviation of symptoms usually occur in 24 to 48 hr after instituting therapy with 2 to 3 Gm daily To avoid relapse treatment should probably be continued for at least 7 days after defervescence The disease will usually respond to penicillin if a daily dose of at least 2 million units is used In severe cases oxygen and other supportive measures are indicated

Section 14 Exanthematous Viral Infections

Robert R Wagner

The exanthematous infections constitute a group of diseases caused by a variety of viruses in which the most prominent clinical feature is skin rash The nature of the rash serves as a basis for dividing these diseases into the *pox group* and the *morbilliform group* The true pox infections of man are smallpox, vaccinia and cowpox chickenpox is caused by an entirely different virus and should be considered a separate entity Present knowledge of the viral diseases characterized by morbilliform or macular eruptions suggests a classification into one subgroup comprised of measles and rubella (German measles) and another of which the prototype is exanthem subitum The latter subgroup consists of an amorphous collection of invariably mild diseases such as erythema infectiosum (Fifth disease) Boston exanthem and undoubtedly a number of as yet unclassified entities Fourth disease (Dukes disease) is sometimes included among the viral exanthems on rather sketchy evidence In addition, dengue and infectious mononucleosis are sometimes classified as exanthematous diseases but because

rash is a less consistent feature of their clinical picture they will be considered elsewhere Morbilliform rash has also been described in infections caused by ECHO viruses

The *history* of the exanthematous diseases is long and confusing At one time all epidemic eruptions (including typhus fever and scarlet fever) were considered to be variants of smallpox Measles was probably first recognized by Rhazes a tenth-century Arabian physician and its identity was finally established by Sydenham in the seventeenth century At about this time chickenpox made its appearance in medical writings but its separate status was achieved relatively recently Rubella or German measles received little recognition as a distinct entity until Koplik in 1896 firmly established the measles exanthem as a definite clinical basis for differentiating measles and rubella The first epidemics of erythema infectiosum were described under a variety of names in 1889 Exanthem subitum (roseola infantum) masqueraded as a variant of rubella and other infantile eruptions until Zahorsky s classic description in 1910 established it as a separate disease Finally Neva uncovered an outbreak of an unusual epidemic exanthem" and renamed it *Boston exanthem* in 1956 The list awaits inclusion or exclusion of a number of ill defined exanthematous diseases

The *viral etiology* of the true pox diseases has been well established for 50 years Smallpox is the human representative of a large family of mammalian viruses that are related serologically and morphologically These viruses also produce similar cellular lesions in a variety of animals Although viruses have long been suspected as the causative agents of the other exanthematous diseases failure to transmit these infections to laboratory animals other than monkeys has hampered definitive investigations Tissue culture techniques have made possible the isolation and serologic identification of the viruses of measles rubella chickenpox Boston exanthem and erythema infectiosum It should be possible in the near future to grow these agents in sufficient quantity to produce protective vaccines and diagnostic antigens

The *epidemiology* of measles rubella and chickenpox is similar They are transmitted by the respiratory route during the prodromal or pre eruptive stage Epidemics are most frequent in late winter and early spring The respiratory tract is also the commonest portal of entry of smallpox virus but in contrast to measles and chickenpox the greatest period of contagiousness is during the eruptive phase Certain epidemiologic features of exanthem subitum erythema infectiosum and Boston exanthem suggest that the respiratory tract is not the main portal of entry for these viruses The respiratory manifestations of these diseases are absent or minimal they have a relatively low degree of contagiousness and cases do not occur predominantly in the winter months In addition the viruses of Boston exanthem and erythema infectiosum have been isolated most frequently from the intestinal tract suggesting a fecal-oral route of transmission

The *pathogenesis* of the exanthematous viral diseases is not completely understood However the classical studies of Fenner on mousepox (infectious ectromelia) an endemic disease of mice that resembles smallpox serve as a model for the pathogenesis of human exanthematous diseases In mouse pox and probably in smallpox (Downie 1954) virus localizes and multiplies at the site of penetration and in adjacent lymph nodes The liver and spleen are also infected in the early stages After a definite interval of time which corresponds to the incubation period virus enters the blood stream from the lymph nodes liver and spleen and is widely distributed to the skin and mucous membranes This stage of viremia coincides with the prodromal symptoms During the next few days antibody is formed and virus disappears from the blood but continues to multiply in the skin mucous membranes and in certain instances the lung and brain This coincides with the stage of major illness characterized by skin eruption and parenchymal lesions of internal organs Measles rubella and chickenpox probably follow a similar pathogenetic pattern but differ slightly in that these viruses infect the nasopharynx only in the initial stage of disease This would account for the fact that these exanthems unlike smallpox are more contagious in the prodrome than in the major illness The pathogenesis of the benign exanthems is unknown but viremia has been demonstrated in Boston exanthem and exanthem subitum suggesting that the skin is infected by way of the blood stream

Immunity to smallpox acquired by vaccination gradually lessens over the years Immunity to the other exanthematous viral diseases is usually lifelong with a few notable exceptions In congenital or acquired defects of antibody production such as agammaglobulinemia multiple attacks of measles and chickenpox can occur It is of interest that these infections are often as mild and self limited in patients with agammaglobulinemia as in individuals who exhibit normal immune responses Chickenpox virus apparently can lie dormant in the tissues for many years flaring up in middle age to produce herpes zoster Difficulty in distinguishing the rashes of measles rubella, and other exanthems probably accounts for most reports of second attacks of these diseases Immunity to each of the exanthematous viral infections is specific and the

rarity of reinfection is evidence that a single major serologic type of virus causes each disease

171 MEASLES (Rubeola, Morbilli)

Robert R Wagner

Definition Measles *is a highly contagious viral* disease characterized by prodromal respiratory symptoms and enanthems (Koplik spots) followed by a typical morbilliform rash

Epidemiology Measles is probably the most contagious of all diseases An isolated community in Greenland where measles was formerly unknown suffered an epidemic in 1951 in which the attack rate was virtually 100 per cent at all ages Epidemics in heavily populated areas are far less dramatic because 95 per cent of individuals above fifteen years of age have been infected previously and are immune Inapparent infections and healthy carriers probably do not occur The peak incidence is in young school children and epidemics recur at intervals of 2 to 4 years as new groups of susceptible children reach school age

Manifestations The clinical course of uncomplicated measles can be divided into three stages the *prodrome* the *eruption* and *recovery* The *prodrome* usually precedes the rash by 2 to 4 days and is characterized by symptoms of increasing fever coryza conjunctivitis photophobia hoarseness and cough The *cough* is deep seated hacking frequently *painful and may persist throughout the* entire illness The pathognomic *Koplik spots* can be found in approximately 95 per cent of cases at the end of the prodromal stage and can persist for a day or two after the onset of rash They are tiny white or bluish white areas on a bright red base characteristically grouped around the orifice of the parotid duct opposite the premolar teeth Occasionally Koplik spots cover the entire buccal mucosa they can also be present on the vaginal mucosa A prodromal rash consisting of transient blotchy *erythema may precede the true rash* The *incubation period* of measles including the prodrome is 12 to 14 days and terminates in the appearance of a *morbilliform rash* At this time fever *increases* cough worsens the face and lips become puffy and the patient appears lethargic irritable and acutely uncomfortable Headache retroorbital pain itching and burning of the eyes marked photophobia and myalgia are common Generalized lymph node enlargement can occur but is less striking than in *rubella Splenomegaly* is occasionally present The rash is first noted on the forehead and behind the ears and soon thereafter on the face and neck Classically it spreads downward in 1 to 2 days to involve the chest back abdomen and limbs including the palms and soles In the early stages the skin lesions are pink discrete macules with slightly raised irregular borders that partially blanch on pressure Later the rash becomes confluent particularly on the face and back and assumes a dusky *red or violaceous hue Rarely it is hemorrhagic* and associated with bleeding from the body orifices (black measles) The eruptive phase generally lasts for 3 to 5 days terminating abruptly with fall in temperature and marked alleviation of all symptoms *Recovery* is usually uneventful The rash fades rapidly leaving a brownish blotchy discoloration of the skin and areas of superficial desquamation

Complications Measles may be complicated by inflammation of internal organs caused by the virus *itself or by secondary bacterial infection Viral bronchitis* and *peribronchial pneumonitis* are quite common and are often mistaken for bacterial bronchitis and bronchopneumonia Viral *interstitial pneumonitis* is relatively rare this complication is characterized by diffuse nodular infiltrations of the lungs often leading to cyanosis and death Abdominal pain and diarrhea may *be manifestations* of invasion of *intestinal mucosa* and *mesenteric lymph nodes* by measles virus True viral *appendicitis* is an uncommon cause of abdominal complaints Gangrene of the face and lips or *noma* has become very rare Slight aberration of *liver function* has been observed but jaundice and hepatomegaly are uncommon Clinical and electrocardiographic evidence of *myocarditis* and *pericarditis* have been reported but their true incidence is unknown Superficial *corneal ulcerations* are often found if looked for carefully these areas usually heal without scarring but severe bacterial keratitis and blindness sometimes occur Unlike rubella there is no conclusive evidence *that measles in pregnancy is a* cause of fetal abnormalities but abortions may occur The most serious viral complication is *measles encephalitis* encountered in about one case in every 1 000 It is usually heralded by high fever drowsiness excitability and convulsions occurring at any

stage of the illness from the prodrome to a week or more after the onset of rash The mortality rate of measles encephalitis ranges from 10 to 30 per cent in different epidemics approximately 40 per cent of survivors show permanent sequelae of mental retardation personality changes and behavioral disorders

Secondary bacterial infections generally develop in the late eruptive stage and although infrequent in this decade are still the major causes of death in measles The most serious pyogenic complication of measles is *bronchopneumonia* which is associated with a high incidence of delayed resolution empyema lung abscess and bronchiectasis Purulent *otitis media* is occasionally encountered but usually does not lead to mastoiditis Rarely *bacteremia* followed by metastatic abscess formation meningitis or endocarditis may occur particularly in infants or debilitated children Paradoxically children with *nephrosis* often undergo a prolonged remission after an attack of measles Positive tuberculin reactions may revert temporarily to negative and exacerbations of latent *tuberculosis* can follow an attack of measles

Laboratory Findings Tissue culture methods for detecting measles virus and antibody are still in the experimental stage at present (1957) The simplest laboratory procedure is the microscopic examination of Wright s stained smears of nasal curettings or sputum for the characteristic multinucleated giant cells of measles (Warthin Finkeldey cells) These cells are most readily found during the late prodromal and early eruptive stages The white blood cell count may be low in the prodromal stage but is usually normal during the rash Leukocytosis occurs in secondary bacterial infections and occasionally in measles encephalitis The cerebrospinal fluid in measles encephalitis contains 0 to 500 cells per cubic millimeter mostly mononuclear cells and a slightly increased amount of protein

Differential Diagnosis In measles the rash cough and systemic manifestations are more pronounced than in rubella and exanthem subitum A problem of ever increasing importance is the differentiation of measles from drug eruptions particularly sensitivity reactions to penicillin

Treatment The treatment of uncomplicated measles is entirely symptomatic A quiet darkened room is much appreciated by the patient with irritability and photophobia Nonproductive debilitating cough is best suppressed by codeine Antibiotics should be administered *only* if secondary bacterial complications develop

Prophylaxis Immune serum is of greater benefit in prevention or attenuation of measles than of any other disease Convalescent serum is effective prophylactically but has the great disadvantage of frequently causing serum hepatitis Gamma globulin prepared from adult human serum always contains measles antibody produces few untoward reactions and is invariably free of serum hepatitis virus The dose of gamma globulin for prevention of measles is 0 1 ml per lb body weight given on the third to eighth day of the incubation period If attenuation is desired 0 02 ml per lb should be given during the first week or larger doses later in the incubation period Doses affording complete protection are advisable for infants or chronically ill children Modified measles usually results in permanent immunity but the aborted disease may not No benefit can be expected by passive immunization in the prodromal or eruptive stage Gamma globulin does not reduce the incidence or severity of measles encephalitis developing in partially protected children

172 RUBELLA (German Measles)

Robert R Wagner

Definition This is a benign contagious disease of viral etiology characterized by fever lymphadenopathy and morbilliform rash Rubella is most important because of the high incidence of congenital malformations following maternal infection in the first half of pregnancy

Manifestations and Diagnosis The incubation period of rubella is usually 18 days with a range of 14 to 23 days A distinct prodromal period is not characteristic of the disease in children although mild fever vomiting and irritability may antedate the rash In contrast to measles rubella usually produces minimal respiratory manifestations Many patients complain of sore gums but there is little objective evidence of gingivitis An exanthem consisting of a circumscribed patch of small dark red macules resembling petechiae located at the junction of the hard and soft palates

is present in many patients (*Forchheimer spots*) but is not so constant as Koplik spots in measles In adults systemic manifestations such as chills fever to 105 F headache pain behind the eyes diffuse muscular aches and lymph node enlargement are often prominent but even severe rubella rarely causes as much discomfort or prostration as does measles The bulbar conjunctiva may be reddened but palpebral conjunctivitis and photophobia are rare The rash first appears on the neck and face as small pink macules which darken and spread downward over the trunk and extremities within 24 hr The lesions tend to remain discrete but may coalesce over the back and buttocks The palms and soles are usually not involved The rash rarely persists beyond the fourth day Fine desquamation and light brown staining of the skin sometimes occur The most characteristic manifestation of rubella is *enlargement and tenderness* of the suboccipital and postauricular lymph nodes which sometimes attain a diameter of 2 cm and are easily visible as well as palpable Mild generalized lymphadenopathy is common and splenomegaly is infrequently found

Complications are rare There is no definite predisposition to secondary bacterial infections Some patients complain of mild joint pain and swelling that may continue for several weeks after rash and fever subside *Thrombocytopenic purpura* associated with skin and mucous membrane hemorrhages has been described *Meningoencephalitis* due to the rubella virus is uncommon and not so severe as measles encephalitis It usually takes the form of a benign aseptic meningitis but fatal encephalitis can occur Peripheral neuritis and retrobulbar neuritis have also been described

The only significant *laboratory findings* are inconstant leukopenia in the preeruptive phase and lymphocytosis sometimes with abnormal lymphocytes in the stage of rash

There is no specific *treatment* and the vast majority of cases recover uneventfully Rarely relapses similar in all respects to the initial attack occur several weeks after apparent recovery

Congenital Rubella Children born to women who contract rubella in the first 4 months of pregnancy are frequently malformed Less commonly maternal rubella also results in abortion or miscarriage The principal fetal organs involved are the eye ear brain and heart singly or in combination Eye disorders consist of cataracts glaucoma and retinitis pigmentosa Malformations of the inner ear result in deaf mutism A variety of cerebral anomalies have been described including microcephaly mental retardation and possibly mongolism

Common congenital cardiac lesions are patent ductus arteriosus and interventricular septal defect The true incidence of congenital malformations following maternal rubella is unknown estimates vary from 10 to 90 per cent depending on selection of cases Physicians are frequently called upon to decide whether therapeutic abortion should be induced This question cannot be answered simply Each case should be evaluated individually after due consideration of psychologic legal and religious factors

Differential Diagnosis In addition to mild measles rubella may simulate scarlet fever and exanthem subitum Early differentiation of rubella and infectious mononucleosis is difficult at times owing to the similarity in rash adenopathy and early blood leukocyte changes

Prophylaxis Girls should be exposed to rubella before they reach the child bearing age Human gamma globulin is generally ineffective in preventing rubella unless it is prepared from rubella convalescent serum

173 CHICKENPOX (Varicella)

Robert R Wagner

Definition Chickenpox is a highly contagious viral disease characterized by a vesicular rash The causative organism is closely related to probably identical with the virus of herpes zoster (p 1061)

Manifestations The disease occurs predominantly in school and preschool children during the late winter and early spring months It is ordinarily a mild illness in this group An *incubation period* of 14 to 16 days is regularly observed although a range of 9 to 23 days has been reported Mild prodromal symptoms such as fever malaise anorexia headache and myalgia may be present for 2 or 3 days However in most instances the initial evidence of illness is rash High fever severe myalgia prostration and occasionally delirium and stupor can occur in adults when the eruption is at its height A macular and erythematous prodromal rash occasionally precedes the true exanthem

The eruption of chickenpox be ns on the upper

trunk as small macules and papules which vesiculate almost immediately The vesicles are superficial and thin walled contain clear fluid and are surrounded by a broad zone of erythema Pruritus is often intense Slight pressure causes some of the lesions to rupture but the majority become pustular and encrusted within 48 hr Crops of vesicles continue to appear for 2 to 5 days producing the characteristic finding of lesions in different stages of development The rash is most extensive on the trunk with relatively few lesions on the face and extremities the scalp is usually involved Occasionally the lesions are extensive confluent umbilicated hemorrhagic or even gangrenous making differentiation from smallpox by inspection alone difficult The skin lesions heal rapidly without scarring unless secondarily infected with bacteria

Small superficial ulcers and vesicles on an erythematous base are frequent on the mucous membranes of the mouth and genitalia Involvement of the larynx and trachea is rare Lesions of the conjunctiva and cornea sometimes lead to scarring and impaired vision Iritis is uncommon Mild lymphadenopathy is frequent swelling of the suboccipital and posterior cervical nodes is striking when scalp involvement is extensive

Complications *Secondary bacterial infections* of the skin and scalp are common Bacterial infections of the respiratory tract usually occur in children after subsidence of fever and the acute stage of the exanthem Although fewer than 1 per cent of patients develop *bacterial pneumonia* the incidence of suppurative bronchitis is somewhat higher

Primary varicella pneumonia predominantly a disease of adults is being recognized with increasing frequency Invasion of the lungs by the virus produces an interstitial pneumonia characterized by edema and necrosis of alveolar walls hemorrhage perivasculitis and a mononuclear inflammatory response Typical intranuclear inclusion bodies have been described in macrophages and in alveolar and pleural cells Pulmonary lesions are more likely to occur in patients with extensive or hemorrhagic eruptions The onset of pneumonitis is usually abrupt with air hunger tachypnea and cyanosis developing soon after the appearance of rash Dry hacking cough is frequent and about one third of the patients produce sputum streaked with blood Chest pain occurs in half the cases and is often pleuritic Examination of the lungs is entirely negative or reveals only scattered fine rales or rhonchi The temperature is moderately elevated or normal but the pulse rate is invariably rapid Arterial hypotension or failure of the right heart may supervene X ray of the chest reveals fine miliary or nodular densities diffusely distributed throughout the lungs The duration and course of the disease are extremely variable most patients improve markedly within 72 hr but in a few patients respiratory insufficiency and roentgenographic changes persist for weeks The mortality rate in recognized cases of varicella pneumonia has been less than 15 per cent

Chickenpox *meningoencephalitis* is primarily a disease of children that resembles measles encephalitis It usually appears on about the fourth day but the time of onset varies from the first to the twenty first day Headache vomiting convulsions and stupor often occur with dramatic suddenness but the temperature rarely rises above 104 F and is frequently normal Ataxia and other signs of cerebellar disease are often conspicuous Meningismus cranial nerve palsies spastic or flaccid paralyses and hemiplegia may also be present The mortality rate is approximately 5 per cent permanent paralysis ataxia and mental retardation occur in 15 per cent of surviving cases

Other viral complications that have been described are myocarditis pericarditis orchitis and thrombocytopenic purpura Chickenpox in pregnancy may result in mild infection of the newborn infant or intrauterine death Typical herpes zoster (p 1081) occasionally occurs in individuals exposed to chickenpox and both diseases may be present simultaneously in the same patient

Laboratory Findings Fluid aspirated from the vesicles often contains multinucleated giant cells and epithelial cells with eosinophilic intranuclear inclusion bodies The lesions of herpes simplex and herpes zoster have an identical histologic appearance The blood leukocyte count in all forms of chickenpox is normal or slightly elevated unless secondary bacterial infection supervenes The cerebrospinal fluid in the encephalitic form of the disease may be normal or may contain up to 3 000 cells per cubic millimeter most of them mononuclear

Differential Diagnosis Chickenpox is readily recognizable in the vast majority of cases by the *history of exposure and the clinical picture* *Confusion* with smallpox arises particularly in adults if the eruption is widespread and hemorrhagic *Primary herpes simplex* infection of the skin (see p 1091) and *generalized vaccinia* (see p 1061) often produce recurrent crops of varicelliform lesions diagnosis of these diseases depends on a history of preexisting eczema and isolation of the specific virus *Rickettsialpox* can usually be differentiated from chickenpox by the characteristic primary eschar severe headache and specific complement fixing antibody response (see p 1031)

Treatment None of the chemotherapeutic agents is effective in chickenpox or its viral complications Local application of calamine lotion or systemic administration of antihistamines is helpful for pruritus Secondary bacterial infections of the skin and respiratory tract should be treated with appropriate

is present in many patients (*Forchheimer spots*) but is not so constant as Koplik spots in measles In adults systemic manifestations such as chills fever to 105 F headache pain behind the eyes diffuse muscular aches and lymph node enlargement are often prominent but even severe rubella *rarely causes as much discomfort or prostration as* does measles The bulbar conjunctiva may be reddened but palpebral conjunctivitis and photophobia are rare The rash first appears on the neck and face as small pink macules which darken and spread downward over the trunk and extremities within 24 hr The lesions tend to remain discrete but may coalesce over the back and buttocks The palms and soles are usually not involved The rash rarely persists beyond the fourth day Fine desquamation and light brown staining of the skin sometimes occur The most characteristic manifestation of rubella is *enlargement and tenderness* of the suboccipital and postauricular lymph nodes which sometimes attain a diameter of 2 cm and are easily visible as well as palpable Mild generalized lymphadenopathy is common and splenomegaly is infrequently found

Complications are rare There is no definite predisposition to secondary bacterial infections Some patients complain of mild joint pain and swelling that may continue for several weeks after rash and fever subside *Thrombocytopenic purpura* associated with skin and mucous membrane hemorrhages has been described *Meningoencephalitis* due to the rubella virus is uncommon and not so severe as measles encephalitis It usually takes the form of a *benign aseptic meningitis but fatal encephalitis can* occur Peripheral neuritis and retrobulbar neuritis have also been described

The only significant *laboratory findings* are inconstant leukopenia in the preeruptive phase and lymphocytosis sometimes with abnormal lymphocytes in the stage of rash

There is no specific *treatment* and the vast majority of cases recover uneventfully Rarely relapses similar in all respects to the initial attack occur several weeks after apparent recovery

174 SMALLPOX, VACCINIA, AND COWPOX

Robert R Wagner

The viruses of smallpox vaccinia and cowpox are closely related Each is capable of producing either local or generalized infection in man depending on the route of exposure and the state of host resistance Smallpox acquired by intradermal inoculation of virus is usually a far milder disease than naturally acquired smallpox This method of producing immunity known as variolation antedates vaccination by several centuries The classical studies of Jenner published in 1798 popularized the use of cowpox pus for active immunization against smallpox The virus used at present (vaccinia) differs slightly from cowpox virus owing either to mutation by human passage or to accidental contamination with attenuated smallpox virus Jenner s *original vaccinia virus rather than cowpox is still* used for smallpox immunization

SMALLPOX (Variola)

Definition Smallpox is a highly contagious viral disease characterized by a diphasic febrile illness and a vesicular and pustular eruption

Manifestations In its classical form (*variola major*) smallpox can be divided into a *prodromal phase* an *afebrile period* of early rash and a stage of *vesicular* and *pustular rash* The *incubation period* is usually 12 days but varies from 10 to 14 days or longer The *prodrome* starts abruptly with shaking chills fever of 104 to 106 F restlessness irritability headache excruciating backache vomiting and prostration A prodromal rash of faint irregular macules may be noted particularly in the axillary and inguinal areas An easily visible eruption at this stage usually portends a severe illness Rarely the prodromal rash is widespread and purpuric an invariably fatal form of the disease known as *black smallpox (purpura variolosa)* Mucous membrane hemorrhages bone marrow depression shock and coma accompany this fulminant illness and death occurs before the vesicular eruption develops

In most cases the initial fever subsides rapidly after 2 to 4 days and the patient seems much improved At this time a macular (followed by a papular) rash appears with individual lesions which gradually enlarge to about 0 5 cm in diameter Over a period of 6 to 10 days the papules progress to become firm multiloculated vesicles and finally painful and pruritic pustules With the appearance of pustular lesions fever and systemic manifestations recur Characteristically the rash of smallpox is concentrated on the face extremities and particularly the palms and soles However in severe infections the eruption is diffuse confluent and hemorrhagic (*variola haemorrhagica*) *Ulcerative* lesions often occur on the mucous membranes of the oropharynx conjunctivas larynx trachea and genitalia The individual lesions evolve in a regular sequence from papules to vesicles and finally to pustules and at each stage all the lesions have the same appearance The deep layers of skin are involved resulting in typical firm shotty nodules During the recovery phase the pustules become umbilicated and crusted as they heal *the deeply* situated pustules leave pitted scars In mild smallpox the lesions are sparser located in the superficial epidermis and heal without scarring they are soft friable surrounded by a red areola and may resemble closely the individual lesions of chickenpox

The *complications* of smallpox are chiefly the result of systemic reactions to the virus *Encephalitis interstitial pneumonia or myocarditis* occur rarely and are similar in many respects to infection of the brain lung or heart with measles or chickenpox virus *Superinfections with bacteria* particularly staphylococci and streptococci are seen occasionally in the late pustular stage These infections take the form of severe often fatal pyoderma or pneumonia

Benign forms of smallpox occur in certain epidemics particularly in Asia and in partially immune individuals *Alastrim (variola minor)* is characterized by low grade fever sparse rash and almost no fatalities It is caused by a virus identical to smallpox virus except for its reduced virulence

Modified smallpox (*varioloid*) is a mild form of the disease in vaccinated individuals infected with virulent virus Under these circumstances temperature elevation is minimal and the rash is less marked evolves more rapidly or may be absent A patient with smallpox modified by vaccination may transmit a fatal infection to a susceptible individual alastrim however is invariably mild

Laboratory Findings Smallpox virus can be isolated from the lesions of the skin and mucous membranes by inoculation of chick embryos mice or rabbits The virus is also present in the blood 1 to 6 days after onset Serum antibodies can often be detected as early as the fifth day of the disease by complement fixation hemagglutination inhibition and neutralization tests The leukocyte count is low in the prodromal phase leukocytosis is usual during the stage of pustular rash even in the absence of secondary bacterial infection

Differential Diagnosis Smallpox is most often confused with severe chickenpox particularly in adults In smallpox the lesions are situated in the deep layers of the skin are homogeneous and are distributed centrifugally The rash of chickenpox is superficial appears in successive crops and is located mainly on the trunk Pustular drug eruptions and erythema multiforme bullosum occasionally mimic smallpox

Treatment No specific treatment is available for the primary viral infection Although success has been reported in prevention of secondary bacterial infections with antibiotics others state that antibacterial therapy has not greatly reduced mortality Vaccination during the incubation period may result in sufficient immunity to attenuate the disease but does not prevent it All individuals in contact with a suspected case of smallpox should be vaccinated forthwith regardless of previous immunization Stringent isolation precautions until the last skin crust has separated are essential in preventing epidemic spread of the disease

VACCINIA

Definition Vaccinia is a skin infection occurring in the course of vaccination against smallpox with living vaccinia virus Generalized vaccinia and postvaccinal encephalitis are rare complications of intentional or accidental vaccination

Vaccination Vaccine is prepared by dermal inoculation of vaccinia virus into calves The processed fluid from the resulting pocks (vaccine lymph) is dispensed in sealed capillary tubes and can be kept at refrigerator temperature for several months without deterioration There are reports that lyophilized vaccines prepared from fertile eggs are effective for years after storage without refrigeration Vaccination is usually performed in the United States by the multiple pressure method When this is properly done the inoculation site is bloodless and confined to an area 1 to 2 mm in diameter Ideally vaccination should be carried out initially at four to six months of age and should be repeated on entering school and at 5 to 10 year intervals thereafter or at any time that exposure to smallpox is suspected

Three types of reaction to vaccination are distinguishable depending on the degree of host susceptibility A *primary reaction* or *take* occurs in previously unvaccinated individuals or when the level of immunity is low It is characterized by the appearance of an erythematous papule at the local site 3 to 5 days after inoculation The papule enlarges into a multiloculated vesicle which pustulates on about the ninth day Constitutional symptoms of fever malaise and irritability as well as local pain and itching are common at this time particularly in children The pustule hardens and dries and a crust is formed which usually separates at the end of the third week leaving a rough pitted scar

Partially immune individuals exhibit an *accelerated* (*vaccinoid*) *reaction* consisting of a less prominent and more rapidly evolving lesion An *immune reaction* reaches its peak in 2 or 3 days and never progresses beyond the stage of erythema and papule Failure to develop any lesion at all after vaccination is *not* an indication of immunity and calls for revaccination with a fresh batch of vaccine

Complications A variety of untoward reactions can occur following vaccination Groups of *satellite lesions* may surround the original inoculation site usually as a result of scratching or careless application of vaccine Accidental *autovaccination* of distant areas may occur from an early primary lesion a particular hazard being conjunctival infection Vaccination sites can undergo secondary bacterial infection Tetanus and syphilis were at one time hazards of vaccination but are now almost completely unknown A *false positive serologic test for syphilis* which may persist for several months sometimes follows vaccination

It is likely that vaccinia virus enters the blood stream after any primary "take" However it is only under unusual circumstances that this results in generalized infection A transient morbilliform rash (*roseola vaccinatum*) is occasionally seen 1 to 2 weeks after vaccination this probably represents abortive disseminated vaccinia Urticarial rashes which may appear at this time have been attributed to allergy to beef protein in the vaccine A more serious although uncommon complication is generalized vaccinia or Kaposi s varicelliform eruption This disorder has been described for the most part in infants and young children but in rare instances

has been seen in adults Unfortunate confusion has arisen from the application of this eponym to the disseminated dermal infections produced by herpes simplex virus in children (see p 1091) The skin lesions of generalized vaccinia are thin walled hemorrhagic bullae that are superficial and heal without scarring The disease is associated with fever prostration and high mortality More than 90 per cent of cases of generalized vaccinia have occurred in children with preexisting skin diseases such as eczema or impetigo The virus is often transmitted accidentally from a recently vaccinated sibling Therefore children with chronic skin disease should be guarded from contact with vaccinia virus An exceedingly rare but often fatal complication of vaccination is chronic *gangrenous vaccinia (vaccinia gangrenosa)* which occurs in children with impaired mechanisms of antibody formation such as agammaglobulinemia In this disorder viremia persists for months causing periodic necrotizing skin lesions Vaccination during pregnancy sometimes results in *congenital vaccinia* and is possibly associated with an increase in abortions

The exact incidence of *postvaccinal encephalitis* is unknown but is variously estimated at one case in 5 000 to 100 000 vaccinations The mean incubation period is 10 to 12 days with a range of 1 to 28 days The disease starts abruptly with high fever headache vomiting and confusion The neurologic manifestations of postvaccinal encephalitis may be limited to transient dizziness irritability and ataxia but disorientation aphasia delirium convulsions stupor and coma are seen in severe cases Nuchal rigidity is common and the cerebrospinal fluid usually shows a moderate increase in mononuclear cells and protein The mortality rate is about 40 per cent but patients who recover are usually free of sequelae Because the characteristic pathologic process is demyelinization the sobriquet of allergic encephalitis has been applied to this disease This complication is rare in infants making it advisable to vaccinate all children before the age of one year

Treatment No treatment is available for the viral complications of vaccinia other than the use of human gamma globulin in chronic gangrenous vaccinia Secondary bacterial infections should be treated with appropriate antibiotics Loose dry dressings covering the vaccination site will reduce the number of suppurative complications more effectively than impregnated occlusive bandages

COWPOX

Cowpox is an endemic disease of cattle which is transmitted to man by contact with infected cows Human disease is characterized by the appearance of single or multiple papules on the hand or other exposed skin areas These gradually enlarge into firm nodules which evolve into deep seated vesicles and pustules Inflammation and brawny edema in the surrounding tissues are frequent and painful Lymphangitis and enlargement of the lymph nodes draining the infected area are also common The disease is sometimes accompanied by fever and a generalized vesicular rash which heals without scarring The local lesion is likely to ulcerate and drain purulent material for a month or longer Serious complications such as encephalitis are exceedingly rare

175 OTHER EXANTHEMATOUS VIRAL DISEASES

Robert R Wagner

Exanthem Subitum (Roseola Infantum)

Exanthem subitum is a sporadic infectious disease of infants and children characterized by a typical sequence of fever defervescence and rash The vast majority of cases occurs between six and eighteen months of age and the disease is rare above the age of eight although a few instances of typical roseola have been reported in young adults Exanthem subitum seldom attacks more than one child in a family and almost never reaches epidemic proportions

The *incubation period* is about 10 days but may be longer Onset is abrupt with high fever frequently reaching 105 to 106 F in a few hours Convulsions are common with hyperpyrexia but in other respects the patient appears surprisingly well There are usually no respirato manifestations

other than slight pharyngeal injection The lymph nodes are somewhat enlarged particularly in the suboccipital and posterior cervical areas Many a physician's reputation has been established by making a correct diagnosis in the preeruptive phase Constant or remittent fever persists for 3 to 5 days and then subsides completely The rash appears suddenly (hence the name *exanthem subitum*) at the time the fever disappears or as much as 36 hr later It consists of small scattered rose pink macules that blanch on pressure The *eruption* is largely confined to the neck and trunk but can involve the face and arms It usually persists for 48 hr and fades rapidly without pigmentation or desquamation The prognosis for complete recovery without sequelae is excellent Secondary bacterial infections and other complications are extremely uncommon but encephalitic manifestations and postconvulsive hemiplegia have occasionally been reported

There are no specific laboratory tests available to aid in diagnosis Leukocytosis during the febrile phase is followed by leukopenia during the eruptive stage

Erythema Infectiosum (Fifth Disease)

This is an uncommonly recognized contagious disease characterized by lack of systemic manifestations and a typical macular rash The manner in which the infection is transmitted is unknown It tends to occur in localized outbreaks particularly in elementary schools with sporadic secondary cases in family groups It has been observed at ages from eight months to forty five years but most cases are found in children from six to ten years old The *incubation period* varies from 4 to 14 days No definite prodrome occurs and the temperature is usually normal or at most transiently elevated to 100 to 102 F Respiratory and gastrointestinal symptoms are conspicuous by their absence A few patients may show slight conjunctival injection pharyngeal erythema or herpes labialis There is no enanthem or lymphadenopathy The disease is readily recognized by the rash which is the only constant manifestation It begins on the cheeks as brilliant rose red spots with well defined raised margins that rapidly become confluent The bridge of the nose is invariably spared sparse discrete lesions extend from the cheeks to the forehead and neck The rash spreads downward in 2 or 3 days to involve the extremities and to a much lesser extent the trunk The most characteristic lesions are seen on the extensor surfaces of the arms and legs and on the buttocks where large red macules separated by narrow rims of normal skin appear and assume a reticular pattern The spots fade from the center outward leaving a lacey network of red lines In the late stages this network may resemble cyanotic marbling (*cutis marmorata*) of the extremities The rash fades completely in 2 to 24 days without desquamation or residual pigmentation *The blood* leukocyte count is normal except for slight eosinophilia in some cases

Boston Exanthem

This is an acute contagious disease of children and their parents characterized by fever and a rubellalike rash The 29 patients observed in two epidemics have ranged in age between two months and thirty six years The *incubation period* varies from 3 to 8 days Fever and systemic manifestations are more marked in adults and the rash is more intense in children In adults the illness usually starts abruptly with shaking chills fever to 104 F headache muscle pains prostration and occasionally abdominal cramps or sore throat The usual findings in children are low grade fever irritability listlessness and anorexia but more often no prodromal symptoms are encountered A variety of lesions including vesicles small punched-out ulceration raised reddened areas or tiny yellowish plaques occur on the pharyngeal mucosa There is no significant lymph node enlargement The febrile or prodromal phase of the disease lasts about 48 hr The rash ordinarily appears during the 24 hr after fever subsides and consists of salmon pink macules about 2 mm in diameter with indistinct borders The lesions tend to remain discrete although they can coalesce and take on a blotchy appearance The eruption predominates over the face and upper chest but frequently extends to the arms buttocks and legs Occasionally the palms and soles are involved The rash subsides after 72 hr and recovery is always uneventful no complications or sequelae have been noted Boston exanthem is most commonly confused with German measles exanthem subitum and "heat rash"

176 LYMPHOCYTIC CHORIOMENINGITIS

Lewis L Coriell

Definition Lymphocytic choriomeningitis is an acute rarely fatal viral disease of man characterized by inflammation of the meninges and choroid plexuses usually accompanied by signs of respiratory tract infection

History In 1925 Wallgren first described the clinical entity of benign aseptic meningitis for which no etiologic agent could be demonstrated Subsequently Armstrong and Lillie (1934) while studying St Louis encephalitis isolated from a monkey brain a virus that they called the *virus of lymphocytic choriomeningitis* This virus was shown to be enzootic in mice and subsequently Scott and Rivers showed it to be the cause of some but not all cases of human "aseptic meningitis An excellent general review is that of Farmer and Janeway (1942)

Etiology The virus is relatively small measuring 33 to 60 μ It is infectious for the mouse guinea pig and monkey and can be propagated in the chick embryo or in tissue culture

Epidemiology This disease accounts for 3 to 5 per cent of the cases of aseptic meningitis Most infections occur in adults between the ages of twenty and forty years There is no sex difference The disease occurs in all parts of the world and cases usually occur singly One epidemic has been proved due to this virus but case to case infection is extremely rare Since the virus usually is not transmitted from man to man one must look elsewhere for the reservoir of infection Several surveys of trapped wild mice indicate that up to 20 per cent harbor the virus and excrete it in their urine The virus has been detected in mice caught in a house where lymphocytic choriomeningitis had developed and it is probable that man is infected by inhalation or ingestion of dried infected mouse urine The disease is particularly common in the late fall and winter presumably because field mice enter dwellings at this time of year

Pathogenesis Laboratory accidents suggest that the portal of entry may be the conjunctiva the upper respiratory tract or the skin The virus can be recovered from the blood during the early stages of the disease or from cerebrospinal fluid during the period of meningeal signs and it has been recovered a few times from the nasopharynx and urine of human patients

Pathologic changes in fatal human cases have been similar to those in laboratory animals viz extensive round cell infiltration of the meninges and choroid plexuses as well as of the liver spleen, and lung Rarely the brain shows perivascular lymphocytic cuffing hemorrhages gliosis and degeneration of nerve cells

Manifestations Usually the onset of meningeal signs is preceded by 1 to 3 weeks of prodromal symptoms simulating grippe or influenza Fever (which may be remitting) chills sore throat, cough and bronchitis are most common Symptoms usually abate for a few days before the onset of headache vomiting stiff neck and photophobia, the illness in such cases being diphasic Meningeal signs may be slight and the patient rarely appears as acutely ill as in bacterial meningitis The course is usually short and complications are rare but sometimes symptoms recur one or more times after a period of apparent recovery Encephalomyelitis may occur with resulting diplopia mental changes and a variety of neurologic signs Erythematous and macular rashes have been reported in a number of cases and pneumonitis evidenced by clinical or x ray signs occurs in about half the cases during the meningeal phase The disease may simulate influenza with no signs referable to the central nervous system Subclinical infections are probably common as shown by the development of virus neutralizing antibodies in the absence of clinical disease

Laboratory Findings Leukopenia is common in the prodromal period but is not a reliable diagnostic aid The cerebrospinal fluid is frequently under normal or slightly increased pressure and contains 100 to 3 000 cells 95 to 100 per cent mononuclear The sugar and chlorides are usually normal and the protein level is slightly elevated although transient lowering of the sugar occurs in a few cases A positive diagnosis can be made only by isolation of the virus from blood or cerebrospinal fluid by intracerebral inoculation of mice or hamsters from a noninfected colony or by demonstration of a rise in serum complement fixing antibodies after the second week or of virus neutralizing antibodies after 6 to 8 weeks

Diagnosis The diseases that can mimic lymphocytic choriomeningitis are listed on p 1071

Treatment The only treatment is symptomatic

Prognosis Recovery is usually complete within 2 to 3 weeks after the onset of meningeal signs Residual neurologic damage may persist after the rare encephalomyelitic form

Cases of fatal progressive arachnoiditis and of fulminating interstitial pneumonia have been described

177 EPIDEMIC VIRAL ENCEPHALITIDES

Lewis L Coriell

Definition The viral encephalitides comprise a large group of arthropod borne neurotropic viral diseases which occur in epidemic form The seasonal incidence geographic distribution insect vectors and animal reservoirs are specific for each of the diseases but their clinical manifestations are often similar

History Encephalitis lethargica (von Economo s encephalitis or sleeping sickness) was the first pandemic encephalitis to be recognized clinically Although a viral agent has never been identified adequate bacteriologic studies were negative and the clinical and pathologic findings were characteristic of viral infections The disease first appeared in Europe in 1915 in the United States in 1918 and sporadic outbreaks continued to occur throughout the world until 1926 Epidemics have not occurred in recent years although isolated cases presenting the same clinical picture have been described

All the other epidemic viral encephalitides have been recognized since 1930 coincident with development of the disciplines of virology It is probable that most of these diseases occurred sporadically in the past when laboratory procedures for their diagnosis were not available The dates of the first epidemic geographic locations and seasonal incidence are shown in Table 97 A more comprehensive historical review of each disease is included in the references at the end of this chapter

Etiology The causative organisms of epidemic encephalitis are small viruses that range in size from 15 to 40 mμ They can be grown in chick embryos or tissue culture or transmitted to experimental animals of which the Swiss albino mouse is the animal of choice The virus of St Louis encephalitis is not pathogenic for guinea pigs or rabbits as are the viruses of the equine encephalitides

Classification of encephalitis viruses is presently based on the geographic locale in which the disease was first described (e g St Louis encephalitis virus West Nile encephalitis virus) Others bear the names of animal disease (e g louping virus of sheep) and still another group is named for the mosquito (e g Anopheles A and B viruses) from which they have been isolated Many of these agents cause encephalitis in experimental animals but their role as human pathogens is obscure Of particular interest are Bwamba fever Semliki Forest Bunyamwera Hammon Reeves or California Ilheus and Anopheles A and B viruses because specific neutralizing antibodies are found in the serum of human beings living in certain areas Encephalomyocarditis virus (E M C) isolated originally from a gibbon with a fatal infection appears to be world wide in distribution and is closely related to Columbia SK Mengo and certain poliomyelitis viruses

Laboratory differentiation of the arthropod borne encephalitis viruses is based largely on complement fixation neutralization and animal protection tests Those that have been studied thus far fall into one of two groups The viruses of Eastern Western and Venezuelan equine encephalitis are related antigenically Another group includes the viruses of St Louis encephalitis Japanese B encephalitis louping ill Russian spring summer encephalitis and West Nile encephalitis as well as yellow fever and dengue

Epidemiology The available data strongly suggest that encephalitis viruses have complicated life cycles in lower mammals birds and arthropods often characterized by inapparent infection Man and the horse appear to be incidental hosts that are unimportant in perpetuating the viruses in nature The diseases are transmitted by biting insects that can harbor viruses for long periods Persistent viremia without manifestations of infection has been demonstrated in migratory water birds which may be responsible for transporting

Table 97 EPIDEMIC VIRAL ENCEPHALITIS

Disease	First epidemic	Virus isolated	Geographic location	Seasonal incidence	Prognosis: Mortality per cent	Prognosis: Sequelae per cent	Size	Vector	Suspected reservoir	Animal disease
Von Economo's (encephalitis lethargica)	1915	No	World wide	Winter Early spring	30	20	?	?	?	?
St Louis (SLE)	1933	1933	Central and western U S	Spring Early summer	5–30	10–40 infants 5 adults	20–30 mμ	Mosquitoes	Chicken mite Mosquitoes?	Unapparent infection with viremia in many vertebrates
Japanese B (? Russian autumn) (? Australian X disease) (Murray Valley)	1924	1936	Japan Java Philippines *Australia Korea* Manchuria Eastern Siberia Indo-China	Summer *Autumn*	45–80	Infrequent (3)	15–20 mμ	Mosquitoes	Horse? Chickens? ?	Horse unapparent infection with viremia in many vertebrates
Western equine (WEE)	1930	1930	Central and Western U S Canada Argentina	Summer	8–15	Rare	25–40 mμ	Mosquitoes	Chicken mite Wild bird mites	Equine animals
Eastern equine (EEE)	1933	1933	Eastern and Central U S and Canada Mexico Cuba Panama Brazil	Summer	65	60	25–40 mμ	Mosquitoes	Chicken mite ?	Equine animals Pheasants
Venezuelan (VEE)	1938	1938	Northern South America and Panama	? Summer	Low?	Rare	?	Mosquitoes (droplet)	?	Equine animals rodents and birds
Russian spring summer (RSSE) (Taiga tick)	1937	1937	Far Eastern provinces of U S S R Europe	Late spring Summer	30	20	15–25 mμ	*Ixodes persulcatus* (wood tick) *I ricinus*	Ticks	Woodland mammals and birds

Japanese B encephalitis from tropical areas where mosquito vectors survive throughout the year Birds are the commonest known hosts of North American encephalitis viruses but the long term reservoir is unknown although bird mites and hibernating mosquitoes have been suspected

Eastern equine encephalitis virus was originally isolated in Massachusetts but is also found west of the Appalachian Mountains and in Mexico Central America and Brazil *Aedes solicitans* is one of the mosquito vectors Infection of pheasants has been an economic problem in the Eastern United States but has not been associated with human disease which usually follows an epizootic in horses

Western equine and *St Louis encephalitis* viruses are found west of the Appalachian Mountains in the United States and Canada as well as in Argentina *Culex* mosquitoes which readily bite birds and mammals are the most important vectors

Japanese B encephalitis virus is found in temperate and tropical zones from Japan China Manchuria Siberia the Philippines and Java to Australia The disease occurs most often in children during the summer and autumn and is transmitted by *Culex* mosquitoes

Russian spring summer encephalitis is a disease of forest workers in the eastern Soviet and Siberian provinces who are exposed to bites of the tick *Ixodes persulcatus* Ticks transmit the virus to their offspring transovarially A milder form of encephalitis occurs in western Russia and eastern Europe where the suspected vector is *I ricinus* the same tick that transmits *louping ill* in Scotland and northern England

Pathogenesis Although man is usually infected through the bite of a blood sucking arthropod a stage of viremia seems to be fleeting and the virus quickly localizes in the central nervous system where it attacks the meninges and the gray and white matter of the brain and spinal cord The lesions produced by each virus resemble each other so closely that specific etiology can rarely be determined by microscopic study alone The meninges may be hyperemic and infiltrated with small mononuclear cells Small hemorrhages occur in the cerebrum basal ganglia midbrain pons or spinal cord Perivascular infiltration with small mononuclear leukocytes may completely fill the Virchow Robin spaces Degeneration and necrosis of neurones with neuronophagia may be marked and in Japanese B encephalitis striking destruction of the Purkinje cells of the cerebellum is observed Endarteritis and small areas of encephalomalacia may be present Focal areas of demyelinization are often prominent but are not confined to perivascular areas as in postvaccinal encephalitis Pulmonary congestion and visceral edema have been noted in fatal cases of eastern equine encephalitis

Clinical Manifestations The clinical picture of the arthropod borne viral encephalitides is extremely variable and is not sufficiently distinctive for each disease to permit an etiologic diagnosis Each virus may cause a variety of clinical manifestations such as (1) meningoencephalomyelitis of severe or mild degree (2) systemic illness (3) abortive infection and (4) clinically unapparent infection Greater mortality and residual damage have been observed in infants and children than in adults suggesting that age factors are more important in determining severity of infection than the specific infecting virus In general the clinical picture is that of an acute infectious disease leading to death or recovery within 2 or 3 weeks Chills may occur at the onset of Japanese B encephalitis and the erythrocyte sedimentation rate is usually elevated Postencephalitic sequelae slowly improve or remain fixed in contrast to the chronic progression typical of the sequelae of encephalitis lethargica

Most cases of encephalitis lethargica occurred in winter or early spring in people between the ages of puberty and forty five years and both sexes were affected equally The clinical manifestations were usually those of an acute febrile illness with predominant central nervous system manifestations Many patients showed progression of neurologic disease for many months The over all mortality was 30 to 40 per cent being higher in the very young and in the aged Fever was absent in some cases diagnosis becoming evident with the gradual development of parkinsonism athetosis salivation and mental changes Two syndromes were seen most frequently first *the somnolent-ophthalmoplegic* type with paralysis of the extraocular and other muscles innervated by cranial nerves oculogyric crises failure of ocular convergence apathy lethargy stupor or coma which persisted for days weeks or months and second the *irritative complex* characterized by hyperkinetic reflexes irritability and exaggerated choreiform or myoclonic movements The most frequent sequelae were "pseudopsychoneurosis" (i e headache irritability insomnia dizziness fatigue and loss of mental power) muscle weakness salivation athetosis spasticity paralysis and parkinsonism

The spinal fluid pressure was usually normal or slightly increased with a slight mononuclear pleocytosis The brain at autopsy was usually grossly normal or slightly edematous and hyperemic with minute hemorrhages in the basal ganglions midbrain and pons Histologic sections showed perivascular mononuclear infiltration neuronophagia focal encephalomalacia and demyelinization It is of interest that present knowledge of the functional relationships of the basal ganglions sprang from studies of postencephalitic parkinsonism

Laboratory Findings The total blood leukocyte count is usually between 10 000 and 20 000 per cubic millimeter with a slight increase in poly morphonuclear leukocytes However in eastern equine encephalitis total counts up to 66 000 with 90 per cent polymorphonuclears have been re corded The spinal fluid pressure is usually moder ately elevated Pleocytosis of 10 to 300 cells is the rule with mononuclear cells predominating In eastern equine encephalitis the total cell count of the cerebrospinal fluid may reach 1 000 per cubic millimeter with many polymorphonuclear leukocytes

An etiologic diagnosis can be established only by isolation of the virus from brain tissue or cerebro spinal fluid or by the demonstration of a significant rise in neutralizing or complement fixing antibodies in the patient s serum during convalescence Virus has been isolated from the blood and spinal fluid in human cases of Venezuelan equine Russian spring summer and Japanese B encephalitis how ever this is not possible in a routine hospital laboratory and for reasons of expense equipment and safety should not be attempted except by trained workers Specimens for virus isolation should be collected aseptically and promptly delivered to the virus laboratory For serologic diagnosis blood should be drawn very early in the disease and a second specimen 3 weeks later The serum should be separated as soon as the clot has retracted and kept frozen until both serums can be tested together

Treatment There is no specific treatment for any of these diseases after symptoms develop None of the chemotherapeutic agents available at present is of benefit Supportive therapy control of con vulsions maintenance of adequate nutrition and good nursing care are essential Physical therapy muscle training and psychotherapy may be valua ble in the treatment of sequelae Treatment with hyperimmune and convalescent serums has not been beneficial

Prophylaxis Formalized vaccines for many of these diseases have been prepared from infected brain tissue culture or embryonated eggs and pro tective effects have been demonstrated in animals Vaccination of horses and mules has proved suc cessful in this country and woodcutters have been protected by a mouse brain vaccine in Russia Laboratory workers and others exposed to special hazards should be vaccinated

Prognosis The rates of mortality and of sequelae are shown in Table 97

178 POLIOMYELITIS

Louis Weinstein

Definition Poliomyelitis is a common acute viral infection which occurs naturally only in man and produces a wide variety of clinical manifestations In its most severe form it involves parts of the central nervous system In most instances the nerv ous system is not invaded infection may take place without apparent illness or it may result in the pro

duction of nonspecific syndromes or in invasion of the nervous system with or without the development of dysfunction

Etiology The causative agent of poliomyelitis is a virus ranging from 8 to 30 mμ in diameter pathogenic for man monkeys and chimpanzees Three antigenically distinct types have been defined type I (Brunhilde) type II (Lansing) and type III (Leon) Although some degree of cross neutralization is demonstrable in highly immunized experimental animals infection in man with one type does not protect against invasion by another Poliomyelitis virus grows well in tissue culture

The viruses of poliomyelitis may remain viable in water or sewage under proper conditions for as long as 4 months They are not killed by ether Merthiolate tincture of Zephiran ethyl alcohol or low concentrations of phenol but are inactivated by heat bichloride of mercury oxidizing agents 2 per cent tincture of iodine ultraviolet light and 10 min exposure to a chlorine concentration of 0 05 ppm

Epidemiology Poliomyelitis is world wide but epidemics have been limited to a relatively small number of areas That the disease is much more prevalent than is suggested by the number of clinically recognized cases is proved by the widespread distribution of neutralizing antibody to the virus in population groups in which it was thought to be rare In areas where infection without involvement of the nervous system occurs about 95 per cent of the disease is clinically unapparent Poliomyelitis occurs mainly in the warm months of the year with the highest frequency from July through September in the North Temperate Zone although it may appear as early as April or as late as December In tropical or subtropical regions the season" may be prolonged

Certain environmental factors are of importance in determining the risk of exposure to poliomyelitis virus and the development of infection In areas of poor sanitation most individuals develop neutralizing antibodies in early childhood whereas in localities where sanitation is good the peak of population immunity is not reached until fifteen years of age or older Urban dwellers become immune earlier than those who live in rural areas In lower income groups evidence of contact with poliomyelitis virus appears at a younger age than in individuals whose financial status is good this may only reflect differences in crowding and sanitation In some parts of the world certain racial groups appear to be more susceptible than others but this is not constant for a particular race in a different area

Poliomyelitis was most common in the preschool child until about 25 years ago In the past quarter of a century however it has been increasing in older age groups in some recent epidemics 25 to 30 per cent of patients have been older than fifteen years of age The increase in adult cases is not due merely to aging of the population or increased reporting of paralytic and nonparalytic cases Young children are still affected more often than adults Paralytic disease has been described in the neonatal period and late in the sixth decade of life but is very uncommon at these age extremes

Pathogenesis Man is the sole reservoir of poliomyelitis virus Human carriers especially those with unapparent infection are most important in transmission of the virus to susceptible contacts history of contact with recognized cases is uncommon Milk has been incriminated as the source of infection in one epidemic

Virus is present in the stool and oropharynx of patients with poliomyelitis regardless of the clinical type of disease It is recoverable from pharyngeal secretions for only a few days but is demonstrable in the feces for several weeks The weight of opinion favors the intestinal tract as the main source from which virus is disseminated The mode of infection is therefore fecal oral the same as that in salmonellosis shigellosis and other enteric infections Very small quantities of stool contain thousands of infective doses of poliomyelitis virus Large quantities of virus are present in sewage drained from areas in which the infection is present The role of the fly in the transmission of poliomyelitis is not settled Flies trapped in areas close to cases of poliomyelitis may carry the virus Food exposed to flies from homes in which poliomyelitis was present has produced the disease in monkeys to whom it was fed Attempts to reduce the spread of disease in epidemics by eradication of the fly population however has not been successful Poliomyelitis is as highly communicable as measles or varicella in individuals under fifteen years of age infection with or without clinical manifestations occurs in 100 per cent of household and 87 per cent of daily contacts

The theory that poliomyelitis virus multiplies only in nervous tissue and reaches the central nervous system only by way of peripheral nerves from the pharynx or intestinal tract has been seriously questioned because of the demonstration of viremia prior to the onset of clinical manifestations Although the exact mechanism still remains to be proved, the following sequence of events has been postulated on the basis of experimental and clinical observations (1) The virus enters by way of the mouth and begins to multiply in the oropharynx and lower intestinal tract It escapes from either area there is no conclusive evidence as to which is more important in transmission The site of viral growth is probably extraneural Virus is present in pharyngeal secretions and stool during the incubation period it has been demonstrated in the feces

as long as 19 days prior to onset of the disease (2) The phase of minor illness (described below) develops in association with the presence of the virus in the blood throat and feces the viremia persisting for only a few days until antibodies make their appearance The following migration of the infectious agent has been suggested Virus in the intestinal tract penetrates the lymphatic channels and enters the blood stream from which it is dis seminated into the interstitial tissue spaces and then reaches the lymph nodes where it may be detected for a period after the stage of viremia There is still some question whether viremia is primary and is followed by invasion of the nervous system or whether it is merely a manifestation of spill over from already infected neural tissues (3) The final *stage in the pathogenesis of poliomyelitis is invasion* of the nervous system This is thought to follow the viremic stage during which the agent gains a foothold in the nervous system in which it multi plies It has been suggested that the virus enters the nervous system from the blood at one point perhaps the area postrema in the medulla ob longata because this is more penetrable than other parts of the brain to dyes injected intravascularly it has also been postulated however that viral in vasion of the nervous system occurs at many points by direct passage of virus from capillaries to neu rones Once the infectious agent has reached the nervous system it spreads along nerve fibers

Central nervous system invasion in poliomyelitis results from the simultaneous operation of two groups of factors (1) those associated with the virus and (2) those related to the host Strains of poliomyelitis virus vary greatly in their ability to invade nervous tissue from the blood or intestinal tract and to destroy neurones Repeated passage in animals or tissue cultures induces changes in invasive capacity without affecting the basic anti genic character of the agent One of the host fac tors important in determining susceptibility to dis ease of the nervous system is type specific neutraliz ing antibody which is present even before the onset of symptoms The early presence of detect able immunity is in favor of multiplication of virus in nonnervous tissue and accounts for the short persistence of virus in the pharynx and blood sites in which antibody is demonstrable The persistence of virus in the nervous system and intestine is probably due to the difficulty which antibody has in reaching these areas

The most important determinant of human sus ceptibility to poliomyelitis is *serum antibody* Pre vious inapparent infection and illness without in vasion of the nervous system are common in areas where the paralytic form of the disease occurs these produce resistance to reinvasion Many chil dren and most adults possess neutralizing antibody for all three types of virus this probably accounts for the relative infrequency of the disease in older age groups Infants under six months old rarely get poliomyelitis because immunity is passively transferred from the mother Babies born to women in the acute phase of poliomyelitis can develop the disease shortly after birth The sex of patients plays a role in determining susceptibility Among chil dren males are affected more often than females the opposite is true in adults *Pregnancy* increases the risk of clinically apparent poliomyelitis Multi parous females are more susceptible than primip aras The disease is somewhat more frequent in the second than in the first or third trimesters *Menstruation* or *ovulation* appears to heighten sus ceptibility *Absence of the tonsils and adenoids* re gardless of the time of their removal is associated with a marked increase in incidence of bulbar polio myelitis *Chilling or physical exertion* after in vasion by the virus leads to more frequent develop ment of paralytic poliomyelitis especially in adults

CLINICAL MANIFESTATIONS DIAGNOSIS AND COURSE

The incubation period of poliomyelitis varies from 3 to 35 days about 80 per cent of cases occur within 6 to 20 days after contact with the virus The disease may assume one of four forms (1) unapparent infection (2) minor illness (3) non paralytic poliomyelitis (4) paralytic poliomyelitis

Unapparent Infection

In families in which a clinically recognized case of poliomyelitis is present other susceptible mem bers usually develop unapparent infection The bulk of infection with the virus of poliomyelitis (95 per cent) occurs in this form There are no symptoms but the virus is present in the pharynx and intes tine It is probably also present in the blood Type specific neutralizing antibody usually develops

"Minor Illness"

The entire course of poliomyelitis may consist of a nonspecific illness without clinical or laboratory evidence of central nervous system invasion this is abortive poliomyelitis Three syndromes have been observed (1) upper respiratory manifestations consisting of fever of varying degree pharyngeal discomfort with or without coryza and reddening and swelling of the lymphoid tissues of the throat (2) gastrointestinal disturbances with nausea vom iting diarrhea or constipation and abdominal dis comfort accompanied by moderate fever (3) grippelike disease with fever and generalized aching of muscle bones and joints resembling influenza Virus can be demonstrated [illegible]

and blood in the early stages of these "minor" illnesses Type specific neutralizing and complement fixing antibodies develop during convalescence

Nonparalytic Poliomyelitis

Nonparalytic poliomyelitis consists of prodromal manifestations signs of meningeal irritation and abnormalities of the spinal fluid The prodrome is similar to that of the "minor" illnesses and is usually present for several days before the onset of other signs it may be entirely absent Stiffness of the neck and back positive Kernig s signs and with severe meningeal irritation leg and neck Brudzinski s signs are present The tripod (patient extends arms behind back with hands on bed for support when sitting up) and Hoyne s signs (head falls back when with patient in supine position shoulders are elevated) can be elicited in paralytic or nonparalytic poliomyelitis but are not pathognomonic The spinal fluid usually contains between 25 and 500 cells rarely as many as 1 000 to 2 000 Very early in the disease there is often a preponderance of neutrophils (up to 80 per cent) within a few days however mononuclear cells predominate The protein is normal or slightly elevated at the beginning of the illness but may increase to between 50 and 100 mg per 100 ml The sugar content is normal or moderately elevated These findings indicate an inflammatory reaction of the meninges but are not diagnostic of poliomyelitis They are also present in healing bacterial meningitis tuberculous meningitis focal embolic encephalomyelitis (subacute bacterial endocarditis) scarlet fever pertussis encephalopathy leptospiral meningitis syphilis mumps meningitis Coxsackie virus infections herpes simplex meningitis infectious mononucleosis *Trichinella* meningitis brain abscess multiple sclerosis tumors of the brain or spinal cord allergic reactions involving the nervous system postinfectious encephalitides "infectious" polyneuritis and lymphocytic choriomeningitis The diagnosis of nonparalytic poliomyelitis on clinical grounds alone is *impossible because the signs symptoms and* laboratory findings are completely nonspecific Viral and immunologic studies suggest that less than 40 per cent of cases of "nonparalytic poliomyelitis" are actually this disease mumps meningitis without salivary gland involvement (p 1083) and Coxsackie virus disease (p 1089) are the two most common differential diagnoses

The course of nonparalytic poliomyelitis is benign Defervescence usually occurs in 3 to 5 days but meningeal irritation may persist for as long as 2 weeks No changes in reflexes or in muscle and cranial nerve function are detectable The white blood count may be as high as 15 000 in the early stage of the disease but is usually normal within 1 week The spinal fluid often shows mononuclear pleocytosis and elevated protein for 2 to 3 weeks after the onset of the disease

Paralytic Poliomyelitis

The syndrome of paralytic poliomyelitis consists of prodromal manifestations ("minor" illness) signs of meningeal irritation abnormal spinal fluid and signs of involvement of motor nerve cells in the spinal cord brain or cranial nerve nuclei resulting in paresis or paralysis of various muscles Lesions may also be present in parts of the nervous system other than anterior horn cells the precentral gyrus the reticular formation in the medulla, the roof nuclei and vermis of the cerebellum Auerbach s and Meissner s plexuses and sympathetic ganglions are usually found to be involved in fatal cases Seldom however are there clinical signs pointing to disease of these parts "Skip" areas are common in spinal paralytic disease e g involvement of the cervical and lumbar cords is often present with no dysfunction of the thoracic portion

Paralytic poliomyelitis may be subdivided into the following types

I Spinal
- *A* Cervical
- *B* Thoracic
- *C* Lumbar
- *D* Any combination of *A* *B* and *C*

II Bulbar
- *A* Upper cranial nerve involvement—III IV V VI VII VIII
- *B* Lower cranial nerve involvement—IX,X,XI,XII
- *C* Involvement of cardiorespiratory centers

III Bulbospinal

IV Polioencephalitis—paralytic or nonparalytic
- *A* Diffuse encephalitis
- *B* Focal encephalitis
- *C* Cerebellar involvement (?)
- *D* Bulboencephalitic disease
- *E* Spinalencephalitic disease

Prodromal manifestations are often absent in paralytic poliomyelitis In some cases the illness is biphasic in character In these cases the disease starts with fever and manifestations of one of the "minor" illnesses After several days all symptoms disappear in 5 or 10 days there is recrudescence of fever the development of signs of meningeal irritation and the appearance of paralysis The commonest prodromal symptoms in adults are generalized muscle and bone discomfort In children upper respiratory tract syndromes are most frequent The spinal fluid findings in paralytic poliomyelitis are the same as those in the nonparalytic disease and bear no relationship to *the severity of* involvement or prognosis It has been stated that the spinal fluid is completely normal in about 10 per cent of cases of poliomyelitis This incidence is

too high because of the inclusion of cases of non paralytic poliomyelitis many of which as pointed out above are instances of some other disease In the writer s experience paralytic poliomyelitis may be accompanied by a completely normal spinal fluid throughout its entire course but this occurs in no more than 0 5 per cent of cases In some patients decrease in number of cells in the spinal fluid is accompanied by a progressive rise in protein which may reach levels high enough to cause confusion with the cytoalbuminologic dissociation observed in infectious polyneuritis

Spinal Paralytic Poliomyelitis In the early stages of spinal paralytic poliomyelitis cramping pain in the muscles innervated by the affected neurones and hyperesthesia of the overlying skin are present The discomfort may be very severe muscle spasm the exact mechanism of which is not clear is usually detectable Paralysis may not appear for some *time after the onset of symptoms In some instances* increase in muscle weakness is very slow in others it becomes widespread within 48 hr Rarely a rapidly ascending paralysis of the Landry type is observed Age is one factor in determining the extent of involvement In children less than five years old paresis of one leg is most common In patients between five and fifteen years of age weakness of one arm or paraplegia is most frequent while in *adults (sixteen to sixty five years old) quadriplegia* is observed most often Dysfunction of the urinary bladder is at least ten times more frequent in adults than in children Paralysis of the muscles of respiration is most common in those older than sixteen years of age Infants younger than one year are subject to very extensive involvement Among adults men develop quadriplegia respiratory paral*ysis and loss of bladder function more frequently than do women Pregnancy does not increase the* severity of the disease unless parturition takes place during the acute phase There is a definite association of inoculation of antigenic materials (triple vaccine for example) with an increased risk of involvement of the muscles around the site of injection

The location of muscle weakness depends on the portion of the spinal cord affected Isolated infection of the cervical thoracic or lumbar areas may be present or two or more parts of the cord may be involved simultaneously The lumbar area is the one most frequently damaged

When the cervical portion of the spinal cord is involved there is paresis or paralysis of *the muscles* of the shoulders arms neck and diaphragm Very early in the disease the reflexes in the arms remain lively they diminish rapidly however and are usually absent by the time paralysis has become established Coarse twitching of the affected shoulder or arm muscles is common With cervical cord disease there is always danger of respiratory paralysis due to spread of the infection to the motor nuclei of the phrenic nerves and medulla

Weakness of the muscles of the chest upper portion of the abdomen and spine follows involvement of the thoracic portion of the spinal cord Difficulty in breathing results from dysfunction of the intercostal and other thoracic muscles The chest wall may be in spasm and may appear rigid despite the presence of only a minor degree of paresis Twitching *of the thoracic abdominal or spine* supporting muscles may sometimes be noted

Disease of the lumbar portion of the spinal cord produces weakness of the muscles of the legs and inferior portions of the abdomen and back Again pain tenderness "spasm and twitching herald the oncoming paralysis and the reflexes are abolished with the development of flaccid paralysis Dysfunction of the iliopsoas muscles indicated by inability *to sit up from a lying position the hip muscles* quadriceps femoris hamstring and gastrocnemii peroneals anterior tibials ten or fasciae latae glutei and sartorious may occur in various combinations In adults complete paraplegia is not infrequent Paralysis of the urinary bladder usually temporary occurs in about one third of patients over sixteen years of age and is rarely observed in the absence of weakness of the legs

The abdominal and cremasteric reflexes usually disappear before muscle weakness is marked in paralytic poliomyelitis and may be absent during the entire course of the disease An extensor plantar response (positive Babinski) has been elicited in a few cases during the first 1 or 2 days but is a rare finding its persistence or late development is incompatible with poliomyelitis Hyperesthesia of the *skin is frequent Sensory loss does not occur Constipation abdominal cramps and meteorism* are common in spinal paralytic poliomyelitis and are due to partial ileus resulting from involvement of the autonomic nervous system and weakness of the abdominal muscles When the disease is severe sympathetic nervous system disturbances with tachycardia hypertension abnormal sweating and cyanosis and coldness of the involved extremities not due to superficial vasospasm are present

Fever in spinal paralytic poliomyelitis is usually present for the first few days of the disease and disappears by lysis In about 90 per cent of cases there is little or no extension of paralysis after defervescence has been established for about 48 *hr In about 10 per cent however progression* of weakness may continue for as long as a week or more and may be of notable degree

Bulbar Poliomyelitis The incidence of bulbar poliomyelitis differs from one epidemic to another and varies between *6 and 25 per cent In patients* subjected to tonsilloade

of onset of the disease and in those in whom the operation was carried out years before the bulbar form of infection is present in about 85 per cent of cases Pure bulbar involvement (without any signs of spinal cord involvement) is commonest in children adults with bulbar disturbances usually have associated spinal paralyses The prodromal manifestations of bulbar poliomyelitis are often the same as in the spinal form The syndromes which develop depend on the area of the brain stem involved and result from damage to the medulla pons and midbrain Signs and symptoms are produced by (1) dysfunction of the upper cranial nerve nuclei (2) damage to the lower cranial nerve nuclei and (3) disturbances of the respiratory and vasomotor regulating centers in the medulla Combined bulbar and diffuse or focal encephalitis or spinal involvement may occur

Upper Cranial Nerve Nuclei–III IV V VI VII VIII Isolated ocular nerve palsies total external ophthalmoplegia pupillary disorders and Horner s syndrome occur There may be unilateral or bilateral involvement of the fifth nerve with difficulty in chewing and closing the mouth as well as deviation of the jaws Paralysis of the seventh cranial nerve is common and usually unilateral the entire face or only the upper or lower parts may be affected Disturbances of vestibular function and deafness resulting from damage to the nucleus of the eighth nerve occur infrequently

Lower Cranial Nerve Nuclei–IX X XI XII Life may be endangered when the muscles of deglutition are paralyzed because of involvement of the nucleus ambiguus in the medulla With involvement of these nerves the voice has a nasal quality and movement of one or both halves of the soft palate is decreased or absent Saliva collects in the hypopharynx because of difficulty in swallowing and not because of excessive secretion Hoarseness and laryngeal stridor follow weakness or paralysis of the vocal cords Unilateral or bilateral weakness of the tongue sternocleidomastoid and trapezius muscles may be present Inability to swallow results in pooling of saliva and food in the pharynx with obstruction to the airway Aspiration of fluid into the larynx reflex spasm of the glottis and abductor paralysis of the vocal cords constitute very serious threats to life Minor or major pareses of the soft palate and pharyngeal muscles are detectable by a nasal quality of the voice

Disease of the medullary respiratory center produces irregularity of the rhythm depth and rate of breathing Respirations are shallow and as the disease progresses are interrupted by longer and longer periods of apnea until breathing stops completely The thoracic muscles and diaphragm are not weak unless spinal involvement is present Hiccoughing is frequent in the early phase of respiratory center dysfunction Hypoxia without visible cyanosis is common and contributes to the intensity of the manifestations In the late stages cyanosis unresponsive to oxygen administration is commonly present and the temperature pulse rate and blood pressure are elevated The final event is usually shock which in the majority of cases is irreversible despite heroic measures

The manifestations of involvement of the circulatory regulating center are a deep cherry red color of the lips flushed florid appearance of the skin a very rapid irregular pulse small pulse pressure when the blood pressure is normal and moderate to severe hypotension Hyperthermia cold mottled clammy skin shallow respiration and anxiety restlessness and confusion appear as the circulatory mechanism becomes progressively more impaired and irreversible shock develops

Polioencephalitis Encephalitic symptoms occur as isolated syndromes or together with bulbar or spinal poliomyelitis The incidence of polioencephalitis is variable one small epidemic in which most of the patients had this type of disease has been described Symptoms of diffuse or focal involvement of the brain may be present The diffuse form is characterized by confusion agitation anxiety with a feeling of impending doom or somnolence Quivering trembling twitching and jerking of the facial muscles and extremities Flushing of the face tremor of the hands and restless movements occur Insomnia may be severe In fatal cases the confusion is marked and progresses to lethargy and death

In focal polioencephalitis there may be clinical evidence of brain damage or the lesion may be silent and demonstrable only at necropsy Visual verbal agnosia myoclonic jerks grand mal convulsions which occasionally persist for a long time after recovery spastic hemiparesis ataxia of one arm or leg and hydrocephalus have been described

The diagnosis of paralytic poliomyelitis can usually be made on clinical grounds The outstanding manifestations are a lower motor neurone lesion of rapid development with flaccid weakness and hypo or areflexia Signs of upper motor neurone disease or decreased sensation are not compatible with poliomyelitis Among the diseases which may cause confusion especially in their early stages are toxic infectious or idiopathic polyneuritis the post infectious encephalitides viral encephalitides trichinosis acute rheumatic fever cerebrovascular accidents with paralysis acute syphilitic meningitis (frequent cranial nerve palsies) meningomyeloencephalitis resulting from sensitization to foreign protein (horse serum rabies vaccine pertussis vaccine) osteomyelitis scurvy acute multiple sclerosis pseudobulbar palsy myalgic meningoencephalitis (Iceland Tallahassee or Coventry disease) spinal epidural abscess or tumor neoplasms of the brain

too high because of the inclusion of cases of "nonparalytic poliomyelitis" many of which as pointed out above are instances of some other disease In *the writer's experience paralytic poliomyelitis may* be accompanied by a completely normal spinal fluid throughout its entire course but this occurs in no more than 0 5 per cent of cases In some patients decrease in number of cells in the spinal fluid is accompanied by a progressive rise in protein which may reach levels high enough to cause confusion with the cytoalbuminologic dissociation observed in infectious polyneuritis

Spinal Paralytic Poliomyelitis In the early stages of spinal paralytic poliomyelitis cramping pain in the muscles innervated by the affected neurones and hyperesthesia of the overlying skin are present The discomfort may be very severe muscle "spasm" the exact mechanism of which is not clear is usually detectable Paralysis may not appear for some time after the onset of symptoms In some instances increase in muscle weakness is very slow in others it becomes widespread within 48 hr Rarely a rapidly ascending paralysis of the Landry type is observed Age is one factor in determining the extent of involvement In children less than five years old paresis of one leg is most common In patients *between five and fifteen years of age weakness of* one arm or paraplegia is most frequent while in adults (sixteen to sixty five years old) quadriplegia is observed most often Dysfunction of the urinary bladder is at least ten times more frequent in adults than in children Paralysis of the muscles of respiration is most common in those older than sixteen years of age Infants younger than one year are subject to very extensive involvement Among adults men develop quadriplegia respiratory paral*ysis and loss of bladder function more frequently* than do women Pregnancy does not increase the severity of the disease unless parturition takes place during the acute phase There is a definite association of inoculation of antigenic materials ("triple vaccine" for example) with an increased risk of involvement of the muscles around the site of injection

The location of muscle weakness depends on the portion of the spinal cord affected Isolated infection of the cervical thoracic or lumbar areas may be present or two or more parts of the cord may be involved simultaneously The lumbar area is the one most frequently damaged

When the cervical portion of the spinal cord is involved there is paresis or paralysis of the muscles of the shoulders arms neck and diaphragm Very early in the disease the reflexes in the arms remain lively they diminish rapidly however and are usually absent by the time paralysis has become established Coarse twitching of the affected shoulder or arm muscles is common With cervical cord disease there is always danger of respiratory paralysis due to spread of the infection to the motor nuclei of the phrenic nerves and medulla

Weakness of the muscles of the chest upper portion of the abdomen and spine follows involvement of the thoracic portion of the spinal cord Difficulty in breathing results from dysfunction of the intercostal and other thoracic muscles The chest wall may be in "spasm" and may appear rigid despite the presence of only a minor degree of paresis Twitching of the thoracic abdominal or spine-supporting muscles may sometimes be noted

Disease of the lumbar portion of the spinal cord produces weakness of the muscles of the legs and inferior portions of the abdomen and back Again, pain tenderness "spasm" and twitching herald the oncoming paralysis and the reflexes are abolished with the development of flaccid paralysis Dysfunction of the iliopsoas muscles indicated by inability to sit up from a lying position the hip muscles quadriceps femoris hamstring and gastrocnemii, peroneals anterior tibials tensor fasciae latae glutei and sartorious may occur in various combinations In adults complete paraplegia is not infrequent Paralysis of the urinary bladder usually temporary occurs in about one third of patients over *sixteen years of age* and is rarely *observed in the* absence of weakness of the legs

The abdominal and cremasteric reflexes usually disappear before muscle weakness is marked in paralytic poliomyelitis and may be absent during the entire course of the disease An extensor plantar response (positive Babinski) has been elicited in a few cases during the first 1 or 2 days but is a rare finding its persistence or late development is incompatible with poliomyelitis Hyperesthesia of the *skin is frequent Sensory loss does not occur* Constipation abdominal cramps and meteorism are common in spinal paralytic poliomyelitis and are due to partial ileus resulting from involvement of the autonomic nervous system and weakness of the abdominal muscles When the disease is severe sympathetic nervous system disturbances with tachycardia hypertension abnormal sweating and cyanosis and coldness of the involved extremities not due to superficial vasospasm are present

Fever in spinal paralytic poliomyelitis is usually present for the first few days of the disease and disappears by lysis In about 90 per cent of cases there is little or no extension of paralysis after defervescence has been established for about 48 hr In about 10 per cent however progression of weakness may continue for as long as a week or more and may be of notable degree

Bulbar Poliomyelitis The incidence of bulbar poliomyelitis differs from one epidemic to another and varies between 6 and 25 per cent In patients subjected to tonsilloadenoidectomy within 30 days

take Attempts to control this problem consist of the liberal administration of fluids decrease of calcium intake acidification of the urine administration of salicylate and mobilization as early as possible

A syndrome resembling rheumatoid arthritis with redness swelling pain and tenderness of the larger joints is observed rarely in the convalescent phase of paralytic poliomyelitis A variety of skin rashes may occur including miliaria seborrhea and purpuric morbilliform or exfoliative eruptions due to drug sensitization Bedsores are common in respirator patients because of the difficulty in moving them about Markedly paralyzed individuals especially those whose life is threatened by respiratory difficulty frequently experience very difficult emotional problems Disorientation acute panic states Korsakoff like syndromes and acute psychoses have been noted Chronic anxiety and depression are almost universal in severely damaged adults and probably reflect merely the sudden impact of a crippling disease with its serious social and economic implications rather than brain damage due to viral invasion

Immunity

One attack of poliomyelitis usually confers a lifelong immunity against reinvasion by the same serotype Both neutralizing and complement fixing antibodies appear early in the disease the latter persist for only several years after infection while the former persist throughout life Theoretically individuals may suffer three episodes of the disease because immunity is strictly type specific Most adults and many children have poliomyelitis without paralysis or even nervous system invasion two or three times as shown by the presence in their serums of neutralizing antibody for more than one virus type This probably accounts for the decreasing frequency of the disease with increasing age There are however well documented instance of two episodes of paralyzing infection separated by a number of years in the same individual Infants may be protected against infection during the first three to six months of life by antibody passively transferred from the mother

Treatment

Cases of "abortive poliomyelitis even if recognized should receive no therapy except for symptomatic relief of the manifestations of the minor illnesses Antibiotics are without value

The management of nonparalytic poliomyelitis involves primarily the relief of the headache pain in the back and spasm" of the legs associated with meningeal irritation Rest in bed with the mattress supported by a board may be of importance in preventing paralysis and is helpful in reducing the back discomfort The application of wet heat in the form of hot packs" to the neck back and thighs produces considerable relief Analgesics such as Demerol and codeine are very useful and are preferable to other morphine derivatives Antimicrobial agents are useless because they have no effect on the primary disease and do not decrease the risk of secondary infection Neuromuscular examination should not be carried out more often than every 3 to 4 days Bed rest is terminated as soon as severe discomfort is absent in order to reduce the risk of phlebothrombosis and pulmonary embolism Every patient thought to have nonparalytic poliomyelitis should have careful assessment of muscle function and an orthopedic follow up study for 2 to 3 months after recovery The purpose of these measures is to detect and correct minor degrees of weakness which may become apparent only when muscles which appear normal at rest are taxed by the exertion of normal physical activity

The treatment of paralytic poliomyelitis involves (1) the use of all measures to spare the life of the patient threatened by involvement of vital areas, (2) relief of discomfort (3) maintenance of weak muscles in as good a condition as possible until normal neuronal function has sufficient time to return (4) immediate recognition and treatment of medical complications (5) prophylaxis and therapy of emotional disorders (6) surgical treatment of correctable defects and (7) social, economic occupational and physical rehabilitation

Patients with paralysis of swallowing loss of function of the breathing muscles pulmonary edema or shock are in great danger of death Dysfunction of the ninth and tenth cranial nerves while leading to complex problems of infection and regulation of caloric water and electrolyte balance is most important because of the danger of fatal obstruction of the airway For this reason it has been suggested that tracheostomy be performed in all such cases However thorough study has indicated that this operation is followed by a much higher incidence of bronchopulmonary infections due to organisms difficult to eradicate with antibiotic agents than occurs when the procedure is not carried out The preferred initial management of swallowing difficulty is postural drainage suction to keep the hypopharynx as free of fluids as possible and maintenance of adequate intake of food and water by nasogastric intubation The prone position takes advantage of the normal forward inclination of the trachea as an aid to drainage Elevation of the foot of the bed 2 to 3 ft from the floor also helps to keep fluids out of the lower respiratory tract Most important is judicious suctioning of the throat carried out by an experienced physician or nurse If in addition, fluid and electrolytes are administered parenterally at first and later by gavage

and spinal cord Coxsackie virus infection the encephalitis of the preicteric phase of infectious hepatitis infectious mononucleosis with neurologic involvement infections due to the enteric cytopathogenic human orphan (ECHO) viruses focal embolic *encephalitis associated with subacute bacterial* endocarditis tuberculous meningitis with hemiplegia or cranial nerve (especially the sixth) palsies and brain abscess Study of these diseases over a period of a few days to a week after onset clarifies the situation in most instances The only positive method of establishing the diagnosis of paralytic poliomyelitis is the isolation of the virus from the stool or pharyngeal secretions (spinal cord or brain at necropsy) and the demonstration of a rise in the level of neutralizing antibody to the isolated strain in acute and convalescent phase serums If virus cannot be isolated the three type strains maintained in tissue culture may be used a significant rise in titer of neutralizing antibody against a specific serotype is diagnostic

Medical Complications of Paralytic Poliomyelitis Paralytic poliomyelitis especially in adults often presents a number of serious and potentially lethal complications These complications occur most frequently when the respiratory muscles are involved *because of involvement of spinal or bulbar motor* neurones they are at times the direct cause of death Disturbances in water and electrolyte balance are common in patients receiving continuous artificial respiration Fever and the sweating which follows enclosure in a tank during the summer months together with vomiting diarrhea inability to take food and disturbances in carbon dioxide related to improperly regulated ventilation produce a series of chemical disturbances the repair of which taxes the ingenuity of the physician Edema and low electrolyte levels often follow overenthusiastic hydration and have been misinterpreted as *evidence of a salt wasting syndrome Myocarditis* is not uncommon in poliomyelitis it is probably due to direct viral invasion ECG changes mainly T and ST T and P R abnormalities are present in from 10 to 20 per cent of cases Interstitial infiltration of the myocardium with round cells and mild muscle changes are not infrequent and occurs in a few cases along with degenerative changes in muscle fibers Verrucous endocarditis involving the mitral valve has been described Severe myocardopathy has been thought to be responsible for death in some cases Hypertension may develop and is produced by two mechanisms (1) transient *elevation* of blood pressure due to hypoxia and (2) persistent hypertension secondary to *hypothalamic involvement* which may become malignant and lead to severe retinopathy convulsions and mental deterioration unless treated

Pulmonary edema and shock the exact pathogenesis of which is not known are usually the terminal events in fatal cases of poliomyelitis Although relatively young adults are involved phlebothrombosis of the legs with or without pulmonary embolism is not uncommon All methods of artificial *respiration* produce hemodynamic disturbances which are countered by reflex mechanisms acting to maintain normal blood pressure and cardiac output When patients are placed in respirators under *negative tank pressure (positive intratracheal* pressure) after hypotension and impending shock are already present the peripheral vascular collapse often is made worse Acute and marked dilatation of the stomach and large bowel perforation of the cecum acute ulceration of the duodenum stomach and esophagus the formation of multiple erosions of the entire gastrointestinal tract with considerable bleeding and paralytic ileus have been observed Marked depression of prothrombin with massive spontaneous hemorrhage occurs in individuals with severe poliomyelitis especially if they are receiving large doses of broad spectrum antibiotics orally Severe bulbar (ninth and tenth cranial nerves) or bulbospinal disease with paralysis of the breathing muscles is accompanied by the risk of major pulmonary atelectases Bacterial *infection is one of the most dangerous complications of* paralytic poliomyelitis Pneumonia is quite common in patients with paralysis of the muscles of respiration or deglutition The incidence of pulmonary infection is greatly increased by tracheostomy and is highest in the respirator case subjected to this operation The organisms involved most often are *Staphylococcus aureus* and gram negative bacteria such as *Proteus Pseudomonas pyocyanea Escherichia coli* and *Klebsiella pneumoniae* many strains of which are not sensitive to the commonly used antimicrobial agents *Chemoprophylaxis is without value in preventing secondary bronchopulmonary bacterial invasion*

The other common site of infection in poliomyelitis is the urinary tract which is exposed because of the necessity for chronic catheterization in patients with paralysis of the bladder chemoprophylaxis even when given together with tidal drainage is usually ineffective Although the symptoms may suggest only cystitis involvement of the kidney is always present The responsible organisms are those usually found in urinary tract infections and are often insusceptible to antibiotics and sulfonamides The renal problem is complicated by the freqeuncy of stone formation which may be responsible for renal colic obstruction of the pelvis and pyonephrosis increase in severity of pyelonephritis renal decompensation hypertension and vascular disease The factors which contribute to renal lithiasis in these cases are immobility with calcium mobilization *infection stasis dehydration and calcium in*

minimizes the possible effect of exercise in increasing the degree of paralysis Daily physiotherapy is usually started 3 to 4 days after complete defervescence has appeared and extension of weakness has stopped Exercise against resistance even that of gravity is thought to be most beneficial by some clinicians In many clinics exercise in water to remove the effects of gravity is standard practice

The physician must be constantly aware of the complications of paralytic poliomyelitis described above because their immediate recognition and treatment are often lifesaving The prevention and treatment of the emotional disorders which accompany severe paralytic poliomyelitis are often best carried out by the attending physicians and nurses Although the help of the psychiatrist is necessary in difficult situations the importance of physicians nurses and attendants who are in constant contact with the patients and are properly oriented towards these problems cannot be overemphasized

Maximal return of muscle function usually is established at the end of 2 years following the onset of paralytic poliomyelitis A review of the clinical problem by an orthopedic surgeon should be carried out if residual palsies remain and a program of surgical rehabilitation should be set in motion Persistent coldness and cyanosis of the lower extremities suggests consideration of lumbar sympathectomy

The impact of paralytic poliomyelitis on the social and economic status of adults is often very severe Every effort must be made to enlist the cooperation of social service agencies to minimize the disruptive effects of the disease Many patients require occupational rehabilitation because of inability to perform the work in which they were engaged prior to being crippled For others the use of devices such as movable splints hooks etc is very helpful in physical rehabilitation if this cannot be accomplished surgically

Prognosis

The over all mortality rate for poliomyelitis is about 5 per cent Patients with the abortive and nonparalytic types of the disease recover completely About 2 to 5 per cent of children and 15 to 30 per cent of adults (increasing with age) with paralyzing infection die When bulbospinal involvement especially with medullary or phrenic and intercostal nerve dysfunction is present the fatality rate varies between 25 and 75 per cent in these cases it is greatly influenced by age and the presence of shock pulmonary edema superimposed infection or other medical complications

Many persons with paralytic poliomyelitis recover completely In a considerable number there is return of muscle function to some degree Only a few remain totally paralyzed It is striking though paradoxical that the more life threatening the disease in the acute stage the more frequent is complete functional recovery if the patient survives Thus paralysis of the respiratory center usually disappears completely Dysfunction of the ninth and tenth cranial nerves is followed by total recovery in most instances although mild palatopharyngeal weakness may occasionally persist for life Paralysis of the muscles of respiration often disappears completely In some cases the final vital capacity although reduced is adequate to maintain ventilation even with moderate physical exertion In very few instances is chronic respirator care necessary Weak extremities regain about 60 per cent of the total strength that they will ever recover in 3 months and 80 per cent within 6 months Improvement may continue for as long as 2 years The final degree of functional return depends on the number of neurones totally destroyed it varies from as low as none to 10 per cent to as high as 100 per cent

Prevention

Because 90 to 95 per cent of cases of poliomyelitis are inapparent or minor infections and are not diagnosed the prevention of the disease by isolation is very difficult The common practice of isolating clinically evident cases is of much greater individual than public health benefit The usual period of isolation is about 2 weeks although virus may be present in the feces for a much longer period Contact with known cases should be avoided Restriction of community activities such as swimming gathering of people etc is not necessary except with large epidemics when it is more effective in allaying panic than in reducing infection Pregnant women should take special precaution because of the increased susceptibility to the disease during pregnancy Tonsillectomy is contraindicated in areas where poliomyelitis is present All individuals with minor illnesses during the poliomyelitis season should limit their physical activity and avoid chilling until all symptoms have disappeared

The use of gamma globulin prepared from pools of normal human plasma has not been strikingly effective as a prophylactic measure in either family or outside contacts However in persons peculiarly susceptible or in a vulnerable position such as pregnant women campers and physicians or nurses accidentally in contact with virus containing materials the administration of gamma globulin may be worthwhile The dose is 0 15 ml per lb body weight the total quantity for adults is 20 ml

Active immunization against paralytic poliomyelitis has been successfully produced by parenteral administration of formalin inactivated strains of the three viral serotypes grown in monkey kidney

most patients have little or no difficulty in this respect In some cases however tracheostomy becomes necessary despite the risks The indications for this operation are (1) abductor paralysis of the vocal cords confirmed by indirect or direct laryngoscopy—this makes the operation mandatory (2) pneumonia with inability to clear the lungs of exudate the opening in the trachea permits easy drainage of the lower airway (3) repeated bouts of major degrees of pulmonary atelectasis requiring tracheal catheterization or bronchoscopy (4) inability to keep the airway relatively free of secretions—this is often purely a matter of availability of a sufficient complement of experienced personnel Using these indications few tracheostomies have been performed in the writer s clinic

The development of respiratory muscle paralysis demands early recognition and treatment Decreased movement of the diaphragms or intercostal *muscles or both indicates the need for frequent* determination of vital capacity When this is reduced to 50 per cent of normal or less on the basis of age and weight artificial respiration must be given with a tank or cuirass type of chest respirator The patient should be informed of the fact that he is to receive this type of treatment and instructed to relax and synchronize as well as possible his breathing with that of the machine The level of negative pressure employed is that which produces a normal tidal volume as measured with a respirometer Arbitrary setting of negative pressures is useless and potentially dangerous because two patients with the same body area and equal decrease in vital capacity often require different negative intratank pressures to produce normal tidal volumes The speed of respiration is adjusted to 12 to 16 per minute and is altered if necessary to suit the comfort of the patient Determinations of plasma CO content and arterial oxygen saturation should be made frequently especially when bulbar disease with pooling of secretion is present because a considerable degree of hypoxia may develop before cyanosis is apparent It is best to administer oxygen to all patients requiring artificial respiration If hypotension is present alternating negative and positive pressures of equal degrees often help in restoring blood pressure to normal level The tank respirator is preferable to the chest type because at the same level of negative pressure it produces a greater degree of ventilation The rocking bed is not an adequate substitute for the tank in the acute stage of respiratory paralysis The electrophrenic respirator is of no value in the management of paralysis of the muscles of respiration because as a result of rapid axonal degeneration the phrenic nerves often fail to respond to stimulation within 24 to 36 hr following onset of the disease The use of antimicrobial agents to prevent secondary bacterial infections in bulbar and respiratory muscle paralysis with or without tracheostomy is *not* beneficial and may in fact be dangerous "Weaning" from the tank respirator should be started after the first day and accelerated as rapidly as possible

The use of the electrophrenic respirator is indicated when the respiratory center is involved Tank respiration may actually increase this type of difficulty Indirect stimulation of one phrenic nerve through the skin is usually sufficient If the need for the electrophrenic respirator is continuous for several days or more the phrenic nerve may be exposed and the electrode applied directly by means of a metal clip

The treatment of infections of the lungs and urinary tract which complicate paralytic poliomyelitis is the same as that employed in these types of disease without nervous system infection The frequency of involvement of antibiotic insensitive or*ganisms necessitates determination of resistance* of the isolated bacteria to a variety of antimicrobial drugs

There is no specific treatment for poliomyocarditis When pulmonary edema supervenes in patients receiving artificial respiration the use of positive intratank pressure or positive pressure breathing through a cuffed tracheotomy tube may be helpful Shock is easier to prevent than to treat Assurance of adequate oxygen saturation prevention of dehydration and early treatment of superimposed bacterial infection are of prophylactic value When marked hypotension develops vasoconstricting agents such as norepinephrine are often very helpful in establishing normotension As a rule however these drugs finally become ineffective as their use is prolonged Plasma infusions may be of some help Hypotension appearing during artificial respiration may respond to alternating positive and negative tank pressures of approximately the same degree

The relief of discomfort is one of the most important problems in the care of paralytic poliomyelitis Hot wet packs diathermy warm baths and dry heat reduce pain due to muscle spasm " Analgesic drugs should be used whenever necessary but morphine derivatives should be avoided Changing the position of paralyzed limbs and moving the patient about in bed are effective in reducing the frequency and intensity of pain

Weak muscles must be maintained in as good condition as possible until neural function returns the time degree and extent of resumption of function are unpredictable but treatment should be continued for at least 2 years This aspect of therapy is best managed by the physiotherapist who has had experience with poliomyelitis Muscle examinations should not be carried out too often in the acute phases of the disease this precaution

The term *street virus* is used to designate the agent of the naturally occurring disease *Fixed viruses* are rapidly multiplying strains used in vaccine production which have lost their infectivity for salivary gland tissue after passage in laboratory animals There is only one antigenic type of the virus

Epidemiology All mammals are potential vectors but carnivores are responsible for most cases in man and animals Virus is present in saliva for several days before symptoms develop and persists until the time of death Rabies is usually contracted from bites occasionally from scratches or abrasions contaminated with infected saliva or rarely by penetration of mucous membranes The principal source of infection in man is the dog but 5 to 15 per cent of human cases are caused by cats or other animals The usual form of the disease in dogs called *furious rabies* is characterized by progressive agitation aimless wandering difficulty in swallowing frothing at the mouth labored respirations feeble bark ataxia convulsions and vicious indiscriminate attacks on all creatures and inanimate objects Paralysis and stupor usually develop 2 to 3 days before death and are the sole manifestation (*dumb rabies*) in about one fifth of infected dogs

Although quarantine killing of stray animals and vaccination are effective in controlling canine rabies large reservoirs of infection exist in wild animals such as the wolf in Eastern Europe and Western Asia the jackal in India and North Africa and the mongoose in South Africa Human and canine rabies caused by bites of rabid foxes is not unusual in the United States and the disease is also found in skunks raccoons coyotes squirrels bobcats mountain lions and other mammals Vigorous control measures have eliminated all foci of rabies in domestic and wild animals of Scandinavia and the British Isles and prevented importation of the disease into Hawaii and Australia

The vampire bat transmits a paralytic form of the disease to cattle and horses and constitutes an important reservoir of rabies in South and Central America Mexico and the West Indies Vampire bats are occasionally nocturnal predators of man attacking silently to take their blood meal without the sleeping victim s knowledge Human rabies acquired from bites of common bats was first recognized in the United States in 1951 to 1953 and subsequent surveys have revealed that the disease occurs in many insectivorous and fructivorous species Isolation of rabies virus from bats was also reported from Yugoslavia in 1956 There is evidence to suggest that bats are the original hosts and constitute the largest reservoir of rabies

Rabies is almost invariably a rapidly fatal infection in all mammals except the vampire bat which can continue to transmit the disease for many months Sudden unprovoked attacks by any animals are rare and should be considered as presumptive evidence of exposure to rabies Human to human transmission is exceedingly rare

Pathogenesis Rabies virus spreads from the site of inoculation along sensory nerve pathways to the posterior columns of the spinal cord if the bite is on the extremities or trunk or by cranial nerves to the brain stem from face wounds The salivary glands intestine pancreas renal tubules and adrenal medulla are involved by extension along the autonomic nerves Viremia may occur Focal inflammation neuronophagia demyelinization hemorrhages and perivascular infiltration by mononuclear cells occur throughout the nervous system but these changes are most marked in the basal ganglions subcortical areas and spinal cord Rabies can be distinguished from other viral encephalitides only if the pathognomonic Negri bodies are found These are eosinophilic inclusion bodies 0 5 to 10 μ in diameter demonstrable in the cytoplasm of nerve cells by special stains In all animals including man they are found in greatest abundance in Ammon s horn of the hippocampus and to a lesser extent in pyramidal cells of the cerebral cortex Purkinje cells of the cerebellum and nuclei of the basal ganglions

Manifestations The *incidence* of rabies in unvaccinated individuals bitten by rabid animals is about 15 per cent but varies from 5 to 70 per cent depending on the amount of virus in the saliva and the location and depth of the wounds It may be difficult to obtain a history of animal exposure if the disease is acquired from minor bites or scratches The *incubation period* is usually 30 to 70 days but can be as short as 10 days or rarely more than a year Short incubation periods occur after face or arm bites multiple wounds or wolf bites Prodromal symptoms of fever of 100 to 102 F headache malaise nausea vomiting sore throat and persistent loose cough are often present for 1 to 4 days The most significant early manifestations in about 80 per cent of cases are tingling paresthesias and dull or stabbing pain at the site of the bite often radiating to the hip shoulder or neck and to distal parts of the involved extremity The wound may be inflamed and excoriated by the patient s scratching The first or *excitement* phase of the disease is characterized by increasing agitation marked restlessness excessive motor activity aimless pacing dysarthria and occasionally visual or auditory hallucinations Episodes of unreasoning fear and rage alternate with profound depression The patient may become destructive wildly apprehensive and combative if restrained but usually does not attack his attendants Spasmodic gross muscle contractions and generalized clonic or tonic convulsions with opisthotonos develop shortly after the onset often precipitated by loud noises bright

tissue culture The vaccine is about 60 to 70 per cent effective against type 1 and 85 to 90 per cent against types 2 and 3 The recommended schedule of inoculation is 1 ml initially followed by 1 ml 4 weeks and 7 months later No antibody is demonstrable in about 20 per cent of patients after the first injection In most individuals without antibody prior to vaccination neutralizing capacity of low degree appears in about 4 to 6 weeks after the first dose of vaccine but falls gradually over the next few months The booster injection 7 months later produces a rapid rise in antibody to high levels Persons immune to a single serotype when first inoculated develop a rapid increase in antibody to all three types

The vaccine does not appear to decrease the incidence of nonparalytic poliomyelitis The duration of protection is unknown Reactions to the vaccine are uncommon headache stiffness of the neck arms and legs which may be accompanied by pain skin hypersensitivity fever sore throat vomiting and pain at the site of injection have been noted Approximately one to three paralytic cases of poliomyelitis appear to be associated with each million injections of vaccine

Experimental studies suggest that immunization with orally administered living virus vaccines produces neutralizing antibodies and protection against infection The strains of poliomyelitis virus used are capable of growing in the intestinal tract but do not invade the nervous system Adequate field trials have not yet been carried out Although the effects of this type of vaccine are promising judgment as to the degree of effectiveness must be reserved

179 RABIES

Robert R Wagner

Definition Rabies (hydrophobia lyssa) is a fatal viral infection of the nervous system transmitted in saliva of rabid animals

History Some of the earliest extant writings contain suggestive references to mad dogs Aristotle (c 335 B C) described the transmission of rabies from dogs to other animals and Celsus (c A D 100) recognized that hydrophobia in man was caused by the bite of a rabid dog The prevalence of the disease in man increased markedly in the eighteenth century following a European epizootic of canine rabies The first effective control measures were instituted in Scandinavia resulting in elimination of the disease there by 1826 Galtier s report in 1879 of transmission of rabies to laboratory rabbits led to the classical studies by Pasteur and his associates of fixed" virus for vaccine production Histologic diagnosis of infection became possible after Negri in 1903 described the characteristic cellular inclusion bodies of the disease

Etiology Rabies virus is infectious for nervous tissue of all warm blooded animals and can also be grown in tissue culture and chick embryos It is rapidly destroyed by heat drying and formalin but can be preserved in glycerol or by freezing

days No treatment is required if the animal remains healthy Immune serum should be administered within 24 hr to all individuals who incur severe or multiple bites regardless of whether the animal shows signs of rabies at the time Every bat bite should be considered to be an exposure to rabies

No specific treatment is available if clinical manifestations develop The patient should be kept in a quiet darkened draftless room and disturbed as little as possible Large doses of barbiturates are more effective than opiates in lessening anxiety delirium and the frequency of pharyngeal spasms and convulsions Parenteral administration of fluids is often required

Prognosis Thus far rabies has been an invariably fatal disease in man However every patient should receive all possible supportive treatment in the hope that the diagnosis is in error

180 HERPES ZOSTER

Lewis L Coriell

Definition Herpes zoster also called *shingles* or *zona* is an acute infectious disease of man It is caused by a virus and characterized by unilateral segmental inflammation of the posterior root ganglions or extramedullary ganglions of cranial nerves and by a painful vesicular eruption of the skin along the *peripheral distribution of the involved nerve*

History The disease was called *zona* (a girdle) by the Greeks because of the bandlike distribution of the eruption about the trunk Bokay (1888) suggested a possible etiologic relationship between zoster and varicella and Lipschutz (1921) defined the specific histopathology of the skin lesions Successful transfer by inoculation of vesicle fluid into *human subjects was first reported by* Kundratitz (1925)

Etiology The virus of herpes zoster is a relatively large virus (204 by 240 μ) It is a strict parasite of man Electron micrographs of vesicle fluid have shown the virus to be similar in size and shape to the virus of varicella The virus may be plentiful in early vesicles but is typically scanty after 24 hr The absence of a susceptible laboratory animal has *hindered immunologic studies*

Epidemiology Infection is less common in children *and increases in frequency severity and duration* with advancing age It occurs at all seasons of the year and is slightly more frequent in males than in females In the United States the majority of but not all patients with herpes zoster give a history of a previous attack of varicella in childhood Epidemics have occurred in schools and barracks but are not common Outbreaks of herpes zoster have occurred in contacts of a patient with varicella and vice versa The grouping of these secondary infections suggests that zoster is infectious only during *the first 2 or 3 days after appearance of the eruption* Secondary zoster following trauma such as spinal puncture administration of arsenic or bismuth spinal cord tumor tabes and lymphatic leukemia have suggested the possibility that the virus may remain dormant in the tissues over long periods of time The disease is more common in persons who are overworked or ill On the basis of the evidence available the viruses of herpes zoster *and varicella are closely related if not identical and* it is tempting to explain the various clinical manifestations by postulating one virus which causes different diseases in the susceptible and the partially immune subject Final solutions of this problem must await the development of new laboratory techniques

Pathogenesis Whether the virus enters the skin and travels up the sensory nerve or extends peripherally *is purely a matter for conjecture at the present* time The virus has been demonstrated only in the skin lesions although an inflammatory reaction is a constant finding in the segmental nerve its sensory ganglion and the posterior horn of the spinal column (posterior poliomyelitis) The regional lymph nodes show an acute inflammatory *reaction The* anterior horn the meninges and the brain may be involved The histologic central nervous system lesions *are infiltration with small round*

lights touch or even drafts Respirations become shallow and irregular the pulse rapid and thready and the temperature usually exceeds 103 F There may be involvement of the autonomic nervous system manifested by dilated irregular pupils excessive lacrimation sweating and salivation Many *patients also exhibit vertigo nystagmus optic neuritis* with central blindness diplopia strabismus or facial palsy Paralysis of the vocal cords results in hoarseness or aphonia Hyperactive deep tendon reflexes Babinski signs and nuchal rigidity are often present

The most characteristic feature of the disease is severe painful *contractions of the pharyngeal muscles* initially *precipitated by attempts to swallow* fluids This usually develops 1 to 3 days after onset and progresses until the mere sight sound mention or even thought of water cause reflex spasms of the muscles of deglutition and respiration leading to bouts of apnea cyanosis and generalized convulsions Most patients manifest a *fear of water (hydrophobia)* and to avoid swallowing allow *frothy saliva to drool from the mouth Death usually* follows a generalized convulsion with prolonged apnea

Patients who survive the excitement stage of the *disease develop generalized flaccid paralysis* often evident at first in the bitten extremity Muscle spasms and pharyngeal contractions cease and agitation gives way to depression apathy hyporeflexia and coma The ability to swallow may return temporarily and there is often transient slowing of the pulse and respirations The bladder usually becomes atonic Generalized paralysis resembling the Guillain Barré syndrome is occasionally the only neurologic manifestation Rabies acquired from vampire bats which frequently bite the toes usually takes the form of Landry s ascending paralysis without excitation or pharyngeal spasm Death usually occurs 2 to 3 days after onset of paralytic rabies but may be delayed for several weeks

Laboratory Findings The blood leukocyte count may be elevated occasionally to 30 000 cells per cubic millimeter with an increased number of polymorphonuclear and large mononuclear cells Glycosuria acetonuria proteinuria and oliguria are present in most cases The cerebrospinal fluid is usually normal but may contain slightly increased amounts of protein and as many as 100 mononuclear cells per cubic millimeter Virus may be present in saliva or rarely in cerebrospinal fluid Serum antibodies can be determined by neutralization or complement fixation tests but serologic studies are of little value because all surviving patients have received vaccine or immune serum Definitive diagnosis is usually made at autopsy by demonstrating Negri bodies or by isolation of virus from the brain

Differential Diagnosis *Hysterical reactions* to dog bites and *allergic encephalomyelitis* caused by rabies vaccine are sometimes difficult to differentiate from rabies Paralytic rabies may be confused with poliomyelitis or the *Guillain Barré syndrome* particularly when a history of animal bite cannot be *obtained or the incubation period exceeds 3 months* Many of the manifestations of *tetanus* except trismus resemble those of rabies *Delirium tremens* and *intoxication with belladonna alkaloids* occasionally simulate rabies

Treatment The basic principle in the treatment of individuals exposed to rabies is to furnish sufficient antibody to prevent the virus from reaching *the central nervous system Semple s vaccine* prepared from fixed virus grown in rabbit brain and inactivated with phenol is commonly used for this purpose in the United States A course of 14 daily inoculations is recommended A potent vaccine free of brain tissue can be prepared in chick embryos from the Flury strain of rabies virus It produces high antibody titers in man and has proved to be *effective for vaccination of dogs and cattle* Passive immunization with antirabies horse serum used as an adjunct to vaccination appears to afford enhanced resistance to infection particularly in heavily exposed individuals The local treatment of bites consists of thorough cleaning with strong soap or detergent solutions and infiltration of the area with immune serum Cauterization or debridement of the wound is no longer recommended

The chief hazards of Semple s vaccine are *hypersensitivity reactions* with severe local erythema, often accompanied by fever and arthralgia in about 5 per cent of cases and *peripheral neuritis* or *allergic encephalomyelitis* caused by the rabbit brain tissue in 1 of 2 000 to 10 000 vaccinated individuals Encephalomyelitis usually occurs 1 to 3 weeks after the first injection of vaccine and is characterized by the sudden onset of chills fever headache and vomiting followed by disorientation dysarthria ataxia paresthesias cranial nerve palsies visual disturbances and frequently hemiparesis or paraplegia Increased concentrations of protein in the cerebrospinal fluid and mononuclear pleocytosis are noted in the majority of cases The mortality rate varies from 0 to 25 per cent and about one third of recovered patients have residual *neurologic* disorders

The decision to proceed with antirabies treatment must depend on the risk of exposure in individual cases Vaccine should be administered promptly if a person is bitten by an animal that escapes is clinically rabid or shows histologic evidence of infection Healthy dogs or cats that inflict minor bites or scratches contaminated with saliva should be impounded and observed for 10

ophthalmic involvement both oral and local antibiotics have been recommended but the choice of antibiotic in this serious complication should be guided by bacterial cultures and sensitivity tests Local treatment of lesions of the globe of the eye should be supervised by an ophthalmologist Early relief of pain and inflammation following cortisone and corticotropin has been reported in a few uncontrolled cases Transfusions of whole blood from persons who have recently recovered from herpes zoster has been abandoned in most clinics In this self limited disease therapeutic regimens based on a small number of observations are apt to be unreliable Severe postherpetic pain may be resistant to all types of management One theory advanced to explain this is the activation of self contained pain circuits in and above the thalamus The following procedures are based on the supposition that the defect is central injection of dorsal root ganglion with alcohol or irradiation with x ray dorsal rhizotomy cordotomy and lobotomy On the theory of peripheral nerve abnormality is based vitamin B therapy procainization or excision of skin, surgical Pituitrin paravertebral block intravenous tetraethylammonium chloride and sympathetic ganglionectomy Other empirical procedures which have also been helpful in certain cases include autohemotherapy sodium iodide moccasin venom and Protamide The multiplicity of recommended procedures is eloquent evidence that none is entirely satisfactory

Prognosis It is very unusual for serious complications to follow inflammation of the spinal ganglions Partial paralysis of the third fourth sixth and seventh cranial nerves or hypesthesia may persist for some time Significant impairment of vision occurs in a high percentage of cases of zoster ophthalmicus

181 MUMPS (Epidemic Parotitis)

Robert G Petersdorf and Ivan L Bennett Jr

Definition Mumps is an acute communicable disease of viral etiology characterized by painful swelling of the salivary glands the gonads meninges and pancreas are sometimes involved

History Epidemic parotitis was described by Hippocrates The disease was produced experimentally in cats by Wollstein in 1918 but it was not until 1934 that its viral etiology was established by Johnson and Goodpasture Habel found in 1945 that the virus could be propagated in the chick embryo and Enders demonstrated complement fixing antibody in the serum of patients convalescent from mumps

Etiology The causative agent of mumps is a virus of intermediate size that closely resembles the influenza viruses in its properties It can be cultivated in the chick embroyo and will agglutinate chicken erythrocytes Mumps virus does not show the tendency to antigenic variation that is characteristic of influenza virus

Epidemiology Mumps is world wide in distribution It is endemic in urban communities although small epidemics frequently occur in settings such as schools camps and barracks Approximately 90 per cent of city dwellers and only 10 per cent of the rural population have been infected Data gathered from complement fixation and skin tests as well as experimental infections in volunteers suggest that at least 40 per cent of human infections are unapparent Man is the only reservoir Infection is transmitted by droplets or fomites The virus is present in saliva and blood for several days before symptoms occur and can persist in salivary secretions for 10 days after the onset of parotid swelling From a practical point of view therefore patients should be isolated until the parotitis has subsided

cells hemorrhage destruction of ganglionic nerve cells and secondary gliosis

The skin vesicle is confined to the epidermis while the corium is congested and infiltrated with inflammatory cells In the margin of the vesicle are epithelial cells undergoing balloon degeneration some of which contain eosinophilic intranuclear inclusion bodies which displace the basichromatin to the periphery of the enlarged nucleus Multinucleated giant cells may be present each nucleus containing an inclusion body Within 2 or 3 days inflammatory cells fill the vesicle and healing progresses from below frequently with slight scarring

Manifestations The incubation period varies from 7 to 21 days A preeruptive and posteruptive stage are distinguished The preeruptive stage consists of fever and constitutional symptoms with pain paresthesias or hyperesthesia over the segmental distribution of the involved nerve for 2 to 4 days Following this an erythematous dermatitis appears which quickly becomes papular and vesiculates with large or small grouped vesicles on an erythematous base The vesicles at first clear become cloudy within 2 to 3 days then crust and dry after 5 to 10 days The eruption may appear first near the spinal column with successive crops over the distal distribution of the nerve The pain and the vesicular band following radicular lines run transversely around the trunk and vertically over the arm and leg The lesions are almost always unilateral Headache and meningismus are not uncommon Pain is frequently slight or absent in young children but may be intense and not completely controlled by analgesic drugs in adults It is variously described as aching soreness burning gnawing shooting stabbing or neuralgic

The regional lymph nodes are enlarged and tender Secondary bacterial infection of the ruptured vesicles is common Over 75 per cent of cases occur between the second dorsal and second lumbar vertebrae and rarely below the elbow or knee Involvement of the fifth cranial nerve is next in frequency and in 50 per cent the globe of the eye is affected When the nasociliary branch of the gasserian ganglion is involved the cornea sclera or ciliary body may be permanently damaged the first branch of the fifth nerve is affected more frequently than the second or third Disease of the geniculate ganglion may lead to zoster of the concha of the ear or the external auditory canal the soft palate and loss of taste (Hunt s syndrome) this is often accompanied by paralysis of the seventh nerve Paralysis is not uncommon in cephalic and cervical zoster but is rare in zoster of the trunk only 44 cases having been reported up to 1943 Second attacks are exceedingly rare and should suggest an alternate diagnosis of localized herpes simplex In some patients a generalized vesicular eruption simulating varicella appears shortly after the appearance of the localized lesion (zoster generalisata)

The total course of the disease from onset to complete recovery is 10 days to 5 weeks Burgoon observed that in the age group up to nineteen years 90 per cent cleared within 14 days while in the forty to fifty nine year age group 45 per cent cleared in this interval If the vesicles all appeared within 24 hr the total illness was short and if crops of vesicles appeared up to 7 days then the total duration was progressively longer A serious complication is the syndrome of postherpetic neuralgia which is limited to the aged with arteriosclerosis It usually involves only the trunk or the ophthalmic division of the trigeminal nerve Frequently there is an interval between the acute phase and full unfolding of severe pain which may be described in various ways by individual patients but is of such persistence and intensity that the patient cannot rest or sleep Pain may persist for weeks or months

Laboratory Findings The fluid from unruptured vesicles is sterile bacteriologically The cerebrospinal fluid is abnormal in 40 per cent of cases pressure may be increased and a pleocytosis of up to 300 mononuclear cells has been observed

Differential Diagnosis In the preeruptive stage the diagnosis is difficult and the disease is usually confused with many other more common causes of pain such as pleurisy appendicitis "lumbago pleurodynia or collapsed intervertebral disk After the unilateral eruption appears the clinical features are so characteristic that diagnosis is simple Occasionally localized herpes simplex along the distribution of a segmental nerve may simulate zoster including the localized pain and tenderness Herpes simplex infection can be confirmed in the laboratory (see Chap 185 p 1091)

Treatment *Treatment is directed at increasing* the patient s comfort and preventing secondary infection The average case of herpes zoster is self limited and presents no serious complications The two unsolved problems are the syndrome of postherpetic neuralgia and ophthalmic zoster In the acute phase pain is usually controlled by aspirin and codeine combined with mild sedation Local anesthetic ointments are not very effective in controlling pain A petrolatum gauze pad bandage to prevent painful trauma by clothing may be helpful The skin lesions are adequately managed with applications of *calamine lotion in most cases* Application of adhesive tape strapping for the preeruptive pain of herpes zoster should be avoided as it will lead to extensive loss of epidermis upon removal of *the tape Antibiotics* have no effect on the virus but may be indicated to control secondary infection particularly in ophthalmic zoster or severe spinal involvement with secondary infection In

increased pressure The protein content is moderately elevated and glucose and chloride are normal In a small proportion of cases however significant lowering of cerebrospinal fluid glucose occurs and this may persist for several days

Usually mumps meningoencephalitis runs its course in a week and leaves the patient without disability The commonest serious residual disability is nerve deafness which fortunately is rare and when it does occur is likely to be unilateral

Rarer Manifestations Inflammation of the lacrimal gland thymus thyroid breast and ovary can occur *Oophoritis* is difficult to diagnose with certainty but can be suspected if lower abdominal pain and fever persist Sterility has never been reported as a complication of mumps oophoritis *Vulvovaginitis uveitis* and *iridocyclitis* have been reported in mumps but it is difficult to be sure that they are caused by the virus *Myocarditis* as evidenced by transient electrocardiographic abnormalities occurs in about 15 per cent of cases but clinical evidence of impaired cardiac function is virtually unknown *Splenomegaly hepatomegaly* and transient *icterus* are seen but are rare and of little significance

A rare but interesting late complication is mumps *polyarthritis* The onset of arthritis is 1 to 2 weeks after convalescence begins and it usually subsides within 6 weeks without residual joint damage

Laboratory Findings In uncomplicated parotitis the blood leukocyte count is normal although a mild leukopenia with a relative lymphocytosis can occur Complications notably orchitis are often accompanied by polymorphonuclear leukocytosis with counts as high as 30 000 per cubic millimeter In meningoencephalitis the blood leukocyte count is ordinarily within normal limits The erythrocyte sedimentation rate is usually normal but often rises with the onset of testicular or pancreatic disease As has been mentioned the serum amylase is elevated in salivary adenitis and pancreatitis serum lipase is elevated only in pancreatitis which can also be accompanied by hyperglycemia and glycosuria

The cerebrospinal fluid contains 0 to 2 000 cells per cubic millimeter predominantly mononuclear The severity of neurologic symptoms bears no relation to the extent of pleocytosis

Transient bilirubinemia and derangement of tests of liver function occur in some patients with mumps but the true incidence of these findings has not been subjected to careful study

The serum complement fixation test becomes positive during the second week of disease and remains so for about 6 weeks Inhibition of viral hemagglutination by convalescent serum is demonstrable later and persists for several months These serologic tests are necessary only in atypical cases or instances of "aseptic meningitis"

Injection of inactivated virus intradermally produces a delayed reaction of the tuberculin type in immune individuals The skin test if positive early in the course of an illness suspected of being mumps is a strong argument against the diagnosis However because skin reactivity appears about 4 weeks after infection and also because the intradermal administration of antigen can stimulate antibody production and make interpretation of complement fixation tests difficult, the procedure is rarely indicated for diagnostic purposes

Diagnosis The diagnosis of mumps during an epidemic is usually obvious Sporadic cases however must be distinguished from other causes of parotid enlargement *Bacterial parotitis* is still seen as a complication in debilitated patients postoperatively and in advanced uremia With suppuration which is common pus can be expressed from the ducts and striking polymorphonuclear leukocytosis occurs *Calculus* in a salivary duct usually detectable by palpation can give painful swelling of the gland *Drug reactions* can produce tender swellings of the parotid and other salivary glands "Iodide mumps is the commonest type mercurialism can also produce this picture Careful history usually serves to clarify the etiology of these reactions *Cervical adenitis* caused by streptococci bull neck diphtheria infectious mononucleosis or cat scratch disease *sublingual cellulitis* (Ludwig s angina) and *cellulitis of the external auditory canal* are usually easy to distinguish from mumps by careful examination Swelling of the parotid produced by *tumor* is usually of long standing The common "mixed tumor" of the parotid is well circumscribed nontender and very firm almost cartilaginous on palpation Parotid swelling and fever often accompanied by lachrymal adenitis and uveitis ("Mikulicz s syndrome") can occur in *tuberculosis leukemia Hodgkin s disease* and *lupus erythematosus* The onset may be sudden but the process is usually painless and lasts for weeks or months "*Uveoparotid fever*" of similar type can be the first manifestation of sarcoidosis however the process in this disease is frequently accompanied by single or multiple palsies of cranial nerves and is referred to as *Heerfordt s syndrome* Finally there is a "primary" type of chronic inflammation of the parotids and other salivary glands often associated with atrophy of the lachrymal glands that occurs most commonly in women past the menopause With cessation of lachrymal and salivary function there may be striking dryness of the conjunctiva cornea (keratoconjunctivitis sicca) and mouth (xerostomia) A variety of systemic manifestations including arthritis of the rheumatoid type has been re

The disease occurs most commonly between the ages of five and fifteen although the age range of reported cases is one to ninety nine years The illness is extremely rare outside the age group of four to forty In Europe and the United States seasonal peaks in incidence occur in the winter and spring

One attack of mumps confers lasting immunity second attacks are exceedingly rare Immunity is just as solid after unilateral as after bilateral parotid involvement

Pathogenesis The upper respiratory tract is the portal of entry and the initial site of multiplication of the virus After an incubation period ranging from 8 to 28 and averaging 18 days virus enters the blood and is widely distributed The salivary glands testes and meninges most commonly show evidence of infection more rarely the pancreas ovary breast thyroid thymus heart liver and cranial nerves are involved

Manifestations *Salivary Adenitis* Parotitis may be preceded by a prodromal period of malaise anorexia chilly sensations feverishness and sore throat Two early findings that suggest the correct diagnosis are tenderness when upward pressure is exerted on the angle of the jaw and reddening and pouting of the orifice of Stensen s duct In many cases the first indication of illness is parotid swelling Usually swelling of one gland is followed within 4 or 5 days by contralateral involvement in about one third of the cases parotitis remains unilateral Swelling of the submaxillary and sublingual salivary glands is common but is often overlooked The enlarged parotid extends from below the ear to the lower portion of the ramus of the mandible and to the inferior portion of the zygomatic arch The skin over the gland may be red and taut Considerable pain and tenderness are present and eating swallowing and talking cause marked discomfort There is swelling and erythema of the orifice of Stensen s duct but no purulent discharge is expressible Sublingual and submaxillary adenitis sometimes give rise to edema of the anterior neck which can extend into the presternal region edema of the glottis can also occur and on rare occasions necessitates tracheotomy

Salivary gland enlargement is maximal in 2 or 3 days and gradually subsides during the ensuing week It is usually associated with malaise headache anorexia and fever of 100 to 103 F However systemic manifestations are sometimes mild or absent particularly in children

Orchitis Mumps is complicated by orchitis in 18 to 20 per cent of postpubertal males This manifestation of the disease usually appears 7 to 10 days after the onset of salivary adenitis although it may precede it or appear simultaneously occasionally orchitis occurs in the absence of parotitis Testicular involvement is unilateral in approximately 75 per cent of patients

Orchitis is usually heralded by recrudescence of malaise and appearance of chilly sensations headache nausea and vomiting True rigors and fevers of 103 to 106 F are frequent The testis becomes greatly swollen and painful The epididymis is often palpable as a swollen tender cord prostatitis and seminal vesiculitis are also common Swelling pain and tenderness persist for 3 to 7 days and gradually subside defervescence parallels subsidence of testicular inflammation Occasionally the fever falls by crisis

Atrophy of the involved testes occurs in at least half the cases and may be apparent within 2 weeks after the acute episode Even after bilateral orchitis sterility is distinctly unusual An association of pulmonary infarction with mumps orchitis has been noted and it has been suggested that thrombosis of veins of the prostatic plexus secondary to the inflammatory process gives rise to emboli

Pancreatitis This is a relatively uncommon but potentially serious complication of mumps Pancreatitis should be suspected in a patient who has abdominal pain radiating to the back tenderness, nausea vomiting and constipation Occasionally a mass can be palpated in the epigastrium or left upper quadrant Peripheral vascular collapse is a rare but ominous complication Serum and urinary amylase are elevated in mumps pancreatitis but are not diagnostic in the presence of salivary adenitis If the parotid swelling has subsided however elevation of serum amylase is indicative of pancreatic inflammation Transient hyperglycemia and glycosuria as well as steatorrhea occur but chronic diabetes mellitus and pancreatic insufficiency are very unusual

Central Nervous System Involvement Involvement of the central nervous system in mumps is common as evidenced by the occurrence of cerebrospinal pleocytosis in nearly 50 per cent of cases Symptoms of severe headache nuchal rigidity and drowsiness occur in only one patient in ten, however severe meningoencephalitis with coma delirium convulsions and cranial nerve palsies is unusual

Meningeal involvement is usually preceded by parotitis but can be the first manifestation or often the only manifestation of infection by mumps virus Indeed serologic studies indicate that 10 to 15 per cent of cases of "aseptic meningitis" in this country are caused by mumps virus For some unexplained reason symptomatic involvement of the central nervous system is three to five times more common in males than in females

The cerebrospinal fluid is clear and under slightly

Section 16 Other Viral Infections

182 YELLOW FEVER

W Elizabeth Gambrell

Definition Yellow fever is an acute infectious disease caused by a virus and transmitted to man by the bite of an infected mosquito Its chief characteristics are fever jaundice bradycardia proteinuria and a hemorrhagic tendency The infection may be mild and almost asymptomatic or extremely severe and rapidly fatal Two types of the disease are now recognized *urban yellow fever* transmitted from man to man by the bite of the mosquito *Aedes aegypti* and *sylvan* or *jungle yellow fever* transmitted to man from an animal reservoir (monkeys) by other species of forest mosquitoes

Etiology The virus of yellow fever is small its size being estimated at 17 to 28 mμ It can be inactivated easily by heat and ordinary antiseptics but can be preserved for months in 50 per cent glycerin and for years in the desiccated refrigerated state Two general types are recognized the *viscerotropic* which involves the liver kidneys and heart and the *neurotropic* which attacks nerve tissue In nature the virus possesses both affinities and is said to be *pantropic* Strains which are predominantly neurotropic grow readily in tissue culture while viscerotropic strains require minced mouse embryo brain medium and chick embryo medium containing nerve tissue The virus can be maintained in the developing chick embryo and by inoculation into the testes of mice The various strains isolated in different parts of the world appear to be antigenically identical

History and Epidemiology Yellow fever occurs in large areas of South America and Africa Since 1948 an epidemic of sylvan yellow fever has been spreading northward through Central America and in the Caribbean area Much circumstantial evidence points to Africa as the place of origin of the disease but the first reported epidemic was in Yucatan in 1648 From that time until the twentieth century many outbreaks occurred in the coastal regions along the trade routes of the Atlantic The disease showed a seasonal incidence being common during the warmer weather and subsiding with the cold weather

Little was known of the method of transmission until Carlos Finley in 1881 incriminated the mosquito now known as *A aegypti* as the vector Because of the high incidence among American troops during the Spanish American War the Yellow Fever Commission was established under the direction of Major Walter Reed In 1900 and 1901 through experiments on volunteers in Cuba Reed Carroll Agramonte and Lazear proved the method of transmission by mosquitoes and showed that the causative agent could pass through a Berkefeld filter thus establishing the virus etiology of the disease Control and suppression of yellow fever followed mosquito eradication

The successful control of outbreaks which followed campaigns against *A aegypti* led to the formulation of the "key center" theory of epidemics by Carter From evidence that one attack of the infection produced a lifelong immunity Carter reasoned that two factors were necessary to keep yellow fever in a community (1) a population of nonimmune human beings and (2) a population of mosquitoes to act as vectors Epidemiologists surveyed the key centers and a tremendous control program was launched under the auspices of The Rockefeller Foundation with the optimistic belief that yellow fever could be eradicated from the Americas and eventually from the world The campaign appeared successful and the disease seemed to be disappearing from South America until a mysterious epidemic broke out in Rio de Janeiro in 1928

In this same year Stokes Bauer and Hudson working in West Africa demonstrated the susceptibility of rhesus monkeys to the virus In 1930 Theiler adapted the virus to white mice by intracerebral inoculations With the acquisition of susceptible experimental animals new tests were available for epidemiologic studies and the whole problem was reevaluated

The Rockefeller Foundation sponsored extensive surveys employing serologic tests and post mortem biopsy studies (viscerotomy service) which demonstrated conclusively that West Africa was not the last remaining key center but that the disease was far more widespread In the jungles and forests in large areas of South America Central America and Africa the disease is present in the monkey population and is transmitted by "forest loving" mosquitoes particularly species of *Haemagogus* This reservoir constitutes a potential source of danger to the native inhabitants and to rural workers who have to go into these areas With increasing air travel and closer communication with all parts of the world the danger of further widespread outbreaks is great particularly in Mexico and along the Gulf of Mexico Eradication of infection by antimosquito measures alone is no longer feasible

Pathogenesis and Pathology The mode of spread and multiplication of the virus has been studied in rhesus monkeys it presumably follows the same

ported in patients with this condition When dryness of the mucosal surfaces is a prominent feature the name *Sjogren s syndrome* is often applied although some insist that *Mikulicz s disease* (as opposed to the *syndrome* accompanying other diseases) is the proper term The chronicity of the process and its occurrence in elderly females makes confusion with mumps unlikely

The diseases that can produce aseptic meningitis are listed on p 1071

When orchitis occurs without parotitis unless mumps is epidemic the etiology is likely to be obscure Serologic testing may later establish the diagnosis of mumps Orchitis is a complication of pleurodynia leptospirosis relapsing fever and rarely of chickenpox In any patient with fever and orchitis brucellosis should be ruled out by appropriate tests (see p 901) Orchitis is a relatively rare complication of gonorrhea

Treatment There is no specific treatment for infections with mumps virus Patients with parotitis should receive mouth care analgesics and a bland diet Bed rest is advisable only as long as the patient is febrile contrary to popular belief physical activity has no influence upon the development of orchitis or other complications

Patients with epididymoorchitis are acutely ill and in great pain Many advocated forms of treatment including surgical decompression of the testicle estrogens convalescent serum and antibiotics have not been beneficial The administration of adrenal steroids in a dosage corresponding to 300 mg cortisone initially followed by a schedule of decreasing dosage for 6 to 7 days has been highly effective in the treatment of orchitis Pain swelling and fever subside dramatically within a few hours in most cases and such measures as suspensories and ice packs are usually unnecessary ACTH hydrocortisone and prednisone are all effective No adverse effect on the course of concomitant meningeal involvement has been noted

The management of pancreatitis is described on p 1477 Adrenal steroids in general have not appeared to alter the course of this complication in any dramatic fashion however in mumps arthritis these hormones have been found to give symptomatic relief

Prophylaxis After exposure to the virus has occurred the administration of gamma globulin is relatively ineffective in preventing or modifying mumps parotitis The use of a formalinized vaccine appears to reduce the incidence of symptomatic infection The disease in children is usually benign and vaccination after exposure is rarely justified However vaccination of exposed adults who show no reaction to skin test with mumps antigen is probably worthwhile

Diethylstilbestrol in a dosage of 1 mg daily for 1 week reduces the incidence of orchitis A preferable regimen is the administration of 20 ml gamma globulin prepared from mumps convalescent serum when parotitis appears

Prognosis Except for rare cases of fulminating encephalitis prognosis for life is good Deafness after meningoencephalitis or permanent diabetes after pancreatitis is rare

measures usually employed For high fever and headache tepid sponges and ice caps are recommended

Prevention Prophylactic measures consist of vaccination and the eradication of *A aegypti* mosquitoes Two strains of attenuated yellow fever virus are available for the preparation of vaccines the French neurotropic and the 17D strain The yellow fever vaccine prepared from the 17D strain consists of macerated chick embryos which have been inoculated with the virus and allowed to harbor it for 4 days The chick embryo juice is desiccated and sealed in ampuls while in the frozen state For use the virus is reconstituted by the addition of sterile physiological saline solution Only one subcutaneous injection of 0 5 ml is necessary to produce immunity in man The 17D vaccine also produces immunity when introduced into the skin by scarification The French neurotropic vaccine is made of dried mouse brain infected with the French neurotropic strain of virus Vaccination consists of applying a gum arabic solution of the vaccine to the scarified skin Mass vaccination has been quite satisfactory In rural areas it is the only effective protection against jungle yellow fever

Before methods of vaccination were developed epidemics were controlled and eliminated whenever the *Aedes* mosquitoes and other vectors were eradicated Breeding of mosquitoes was controlled in and near dwellings by pouring oil into the containers where larvae were found The use of DDT spray on the walls of houses is now an effective preventive At present no method is available for eradicating jungle yellow fever

183 PLEURODYNIA (Coxsackie B Disease)

Robert R Wagner

Definition This is an acute infectious disease caused by Coxsackie group B viruses and characterized by sudden onset of paroxysmal lower thoracic and abdominal pain and fever Common synonyms are *Bornholm disease epidemic myalgia* and *devil s grip*

Etiology Coxsackie viruses are primary intestinal parasites of man that resemble poliomyelitis viruses in size and in their resistance to heat and chemicals but differ in their characteristic pathogenecity for suckling mice and their affinity for striated muscle and fat There are many antigenic strains that are divided into two groups A and B on the basis of the histologic appearance of lesion in suckling mice Most group B and a few A strains can be grown in tissue culture and several also produce cardiac cerebral and hepatic lesions in infant mice and pancreatitis in infant or adult mice Group A Coxsackie viruses are the etiologic agents of herpangina (p 1091) but are otherwise relatively unimportant as human pathogens Group B viruses cause pleurodynia certain cases of aseptic meningitis and nonspecific febrile illnesses

Epidemiology Pleurodynia is a disease of the summer and autumn that occurs in epidemic form throughout the world All age groups are affected but the highest incidence is in children and young adults Explosive outbreaks with extremely high attack rates have been reported particularly in institutions but it is more usual for epidemics to start insidiously reach a peak in several weeks and subside over a period of months Multiple cases in a single household are infrequent indicative of a predominance of asymptomatic infections and carriers Infection is spread by close personal contact probably by the fecal oral route through fomites food and water Other modes of transmission are suggested by isolation of Coxsackie viruses from respiratory secretions sewage and flies

Pathogenesis The virus presumably invades the body from the intestinal tract and has been recovered from blood skeletal muscle cerebrospinal fluid spinal cord and myocardium Autopsies of the few fatal cases reported in infants have revealed extensive myocarditis focal degeneration and inflammation of brain and spinal cord and hemorrhagic lesions of the pleura Degeneration and focal inflammation have been noted in skeletal muscle obtained by biopsy

Manifestations The incubation period is usually 2 to 5 days but may be as long as 2 weeks Mild prodromal symptoms such as malaise sore throat coryza anorexia or myalgia may be present for

course in man although the virus has been isolated only once from a patient after death from yellow fever In monkeys it is primarily an infection of *the hematopoietic system and secondarily invades* other organs When inoculated intradermally the virus spreads immediately to the local lymph nodes where it multiplies After a few days it enters the blood stream and invades the liver spleen kidneys bone marrow and lymph nodes where it can be demonstrated several days after the blood stream no longer contains it

The pathologic lesions can be explained on the basis of infection and multiplication of the virus The organs which show the chief signs of degeneration are the liver kidneys and heart Hemorrhages and jaundice are present in the skin and mucous membranes The liver is normal or slightly enlarged and appears yellow and fatty when sectioned The kidneys are swollen and tense and also have a yellow fatty appearance The heart shows few gross abnormalities but cloudy swelling and patchy fatty degeneration are demonstrable on section The stomach usually shows erosion and punctate hemorrhages in the mucosa of the pylorus

Microscopic changes are most apparent in the liver The liver cells show marked midzone necrosis with fatty degeneration In severe cases entire lobules may show necrosis The Kupffer cells are enlarged and granular and the sinusoids are engorged The architecture remains intact and normal cells may be found about the central vein and the periphery of the lobule There is complete absence of inflammatory reaction

The lesions in the kidney are most evident in the tubules chiefly the convoluted portion where cloudy and fatty degeneration is present In the spleen as in the liver inflammatory reaction is absent

Manifestations The *incubation period* is 3 to 6 days The onset is usually sudden and acute sometimes with a chill but it may be insidious During the first 2 days of illness the chief symptoms are fever headache and backache Temperature rises moderately on the first or second day *Active congestion* follows characterized by flushed face and injected conjunctivas and scleras Nausea and vomiting are common

As the fever reaches a peak the pulse slows Jaundice and evidence of hemorrhage occur on the fourth or fifth day of illness Jaundice even in severe cases is not intense Subcutaneous hemorrhages may occur as petechiae or patchy ecchymoses and gingival bleeding is common Hemorrhages may occur in the stomach and intestine giving rise to black vomit and melena After 3 or 4 days of illness the temperature may fall and a remission of symptoms take place for a short time to be followed by a recurrence of fever

Proteinuria occurs early in the disease and the volume of urine tends to decrease Recovery begins about the seventh day it is rapid and usually without complications

There is wide variation in the severity of the disease from mild or subclinical infections to fulminating fatal cases with hemorrhages and icterus The over all mortality is estimated at 5 per cent Most deaths occur on the sixth or seventh day The characteristic signs whether in mild or severe cases are the rise and remission of fever the slow pulse in relation to the temperature (Faget s sign) and leukopenia

Laboratory Findings Proteinuria is marked in severe cases but is often absent in mild infections A terminal anuria may occur The leukocyte count falls steadily from the onset of infection leukopenia being most marked on the fifth or sixth day There is a decrease in both polymorphonuclear leukocytes and lymphocytes *As reflected in liver function* tests the liver is the organ most extensively damaged by the virus

Three laboratory procedures are available to establish a positive diagnosis isolation of the virus serologic tests which demonstrate development of specific antibodies during an infection and histologic examination of biopsies of the liver Isolation of the virus is possible by intracerebral inoculation of mice with serum from patients up to the fifth day of the disease The inoculated mice develop signs of encephalitis and the agent isolated must then be identified This is usually done by neutralization tests with specific immune serum against yellow fever Serum from patients may show positive protection tests in mice Two specimens are necessary one obtained as soon as possible after onset and a second obtained during convalescence Since antibodies develop very rapidly both specimens of serum must be titrated for their neutralizing property If the antibody content of the serum is higher during convalescence this indicates that the infection is probably yellow fever If the antibody content is the same in both specimens the patient probably has had a previous infection of yellow fever

Liver sections may be obtained by biopsy or in fatal cases in countries where the disease is endemic by the viscerotome This is a simple instrument which permits removal of small specimens of liver after death In South American countries where jungle yellow fever occurs over a large area the study of liver sections of any fatal febrile case of less than 10 days duration is a very important function of the Yellow Fever Service

Treatment No specific treatment is available Bed rest good nursing care and supportive therapy consisting of soft diet adequate fluids and saline and glucose infusions are the general therapeutic

184 HERPANGINA (Coxsackie A Disease)

Robert R Wagner

Definition This is a benign infectious disease of children characterized by sudden onset fever sore throat, and oropharyngeal vesicles

Etiology and Epidemiology Herpangina is a disease of the summer months caused by Coxsackie A viruses (see p 1059)

Manifestations Children under four years of age are most susceptible but the disease also occurs in older children and young adults The incubation period is usually 4 days but varies from 2 to 9 days Prodromal symptoms are uncommon and the onset is usually abrupt with fever of 100 to 105 F Anorexia vomiting abdominal pain and occasionally diarrhea may be present The most common complaint in older children is sore throat often accompanied by dysphagia and salivation Other respiratory symptoms are conspicuously absent and headache and myalgia are uncommon The only noteworthy physical findings are diffuse pharyngeal injection without exudate and the presence of from 2 to 20 small vesicles on the anterior faucial pillars soft palate uvula, pharynx and rarely on the tongue mouth or tonsils The lesions are from 1 to 2 mm in size grayish white in appearance and surrounded by a bright red areola They gradually enlarge to 3 to 4 mm in size and rupture leaving clean superficial punched-out ulcers The cervical lymph nodes may be slightly enlarged and tender Typical vesicles containing virus have also been described on the vaginal labia Febrile diseases without oropharyngeal vesicles are frequent during outbreaks of herpangina and probably represent abortive Coxsackie A infections Diseases in children known as 3-day fever" and epidemic summer grippe and sore throat are also thought to be related to herpangina

Fever persists for 1 to 4 days and *recovery* is always uneventful No *treatment* is required other than mild local anesthetics such as butycaine trochees

Laboratory Findings The blood leukocyte count is moderately elevated in about one fourth of the cases Virus is usually present in the feces and pharynx and serum antibodies develop during convalescence However the multiplicity of strains of Coxsackie A viruses and corresponding antibodies and their prevalence throughout the normal population make laboratory diagnosis difficult costly and time consuming

Differential Diagnosis Primary herpetic stomatitis caused by herpes simplex virus (p 1092) may also involve the oropharynx but unlike herpangina it does not occur in epidemics and lesions are more common on the gums and anterior part of the mouth The enanthems of measles and chickenpox aphthous stomatitis and bacterial pharyngitis may be confused with herpangina at first but are readily differentiated by their subsequent course (see p 852)

185 HERPES SIMPLEX

Lewis L Coriell

Definition Herpes simplex is an infectious disease caused by a virus Classically it appears in recurrent attacks as clusters of grouped vesicles on an erythematous base having a predilection for the face lips and mucocutaneous junctions The initial infection in some individuals may be more serious or even fatal Infection of the central nervous system the eye the skin in eczematous patients the viscera or the mouth and throat in gingivostomatitis are the common forms of "primary herpes simplex

History Gruter in 1914 first transferred infection from the cornea of a patient to the cornea of a rabbit and subsequently back to the cornea of a blind man reproducing a typical dendritic ulceration of the cornea In 1938 Dodd Buddingh and Johnson isolated herpes simplex virus from the mouths of children suffering with febrile ulcerative stomatitis (acute herpetic gingivostomatitis) Burnet (1939) found no neutralizing antibodies in the acute serum from similar patients and antibodies developed during convalescence In 1941 a serious complication of eczema Kaposi s varicelliform eruption was shown to be caused in some cases by secondary infection of the abnormal skin with the virus of herpes simplex (eczema herpeticum)

Etiology The virus of herpes simplex passes ordinary bacterial filters quite readily and measures 125 to 150 mμ in diameter It is present in early vesicles It may be propagated on the cornea or in the brain of several laboratory animals on the

several days However the most characteristic feature of the disease is the sudden onset of severe sharp paroxysmal pain over the lower ribs or in the substernal area It is accentuated by moving breathing coughing sneezing or hiccuping and may be referred to the shoulders neck or scapulae Pain and spasm of the anterior abdominal muscles occur in about half the cases often in combination with chest pain but sometimes localized entirely to the lower abdomen Muscle tenderness is usually not prominent but some patients complain of intense cutaneous hyperesthesia and paresthesias over the affected area Headache is frequently present sometimes of excruciating severity and may be accompanied by delirium dizziness and true vertigo Fever of 100 to 105 F develops shortly after the onset of pain and is often preceded by chilliness or shaking chills The temperature may be elevated in the early morning fall to normal at midday and rise again in the evening Respiratory manifestations are not prominent but there may be mild pharyngeal injection and nonproductive cough Conjunctivitis and photophobia are rare A pleural friction rub is detectable in 10 to 25 per cent of patients and can persist after the pain subsides Transitory erythematous rashes have occasionally been noted Anorexia and nausea are frequent and vomiting and diarrhea often occur in children

Certain outbreaks of Coxsackie B viral infections have been characterized by a preponderance of nonspecific febrile illnesses without thoracic or abdominal pain Sore throat generalized lymphadenopathy splenomegaly and fever lasting for 2 to 14 days have been reported in children Another type of illness seen in adults is characterized by pain and tenderness of the neck occiput back shoulders or extremities The relationship of Coxsackie infections to epidemic fibrositis a disease with similar manifestations which occurs predominantly in the winter has not yet been determined

The complications of pleurodynia are largely the result of disseminated infection with the causative virus *Meningitis* can occur several days after the onset of pain and fever or it may be the sole manifestation of infection indistinguishable from other forms of benign aseptic meningitis Coxsackie meningitis occurs more frequently in children than in adults and is often a biphasic illness The incidence of *pericarditis* is unknown but *myocarditis* has been described in infants in association with *encephalitis* *Orchitis* developing in the second week of the disease has been a frequent complication in certain outbreaks but is rare in others Arthritis and jaundice have also been reported Otitis media and herpes febrilis are uncommon complications The average duration of illness is 4 days but varies from 1 day to several weeks *Relapses* occur in 25 to 50 per cent of cases usually 2 to 3 days after subsidence of the initial episode but sometimes after an interval of several months Some patients experience multiple attacks of equal severity Complete recovery may be delayed for weeks by generalized weakness but convalescence is otherwise uneventful and there are no known sequelae Deaths directly attributable to the infection have been reported only in infants with myocarditis Immunity is type specific and reinfection can occur with other types of Coxsackie virus

Laboratory Findings Isolation of Coxsackie B virus from the feces or throat washings does not constitute valid proof of infection unless supported by epidemiologic evidence Definitive diagnosis can be made only by demonstrating a rising titer of neutralizing or complement fixing antibodies in the serum This is a formidable and often unrewarding procedure because of the many strains of virus and the high incidence of asymptomatic infection X ray of the chest is normal except for rare instances of pneumonitis or pleural effusion The blood leukocyte count is usually normal but can be low or moderately elevated Slight eosinophilia sometimes occurs several days after onset or in convalescence The cerebrospinal fluid may be normal or may contain as many as 300 cells most of them mononuclear

Differential Diagnosis Pleurodynia is often confused with early bacterial pneumonia when pain is localized to the chest and with intra-abdominal disease particularly acute appendicitis when abdominal pain predominates In the absence of characteristic pain Coxsackie meningitis can be differentiated from other benign aseptic meningitides only by appropriate laboratory studies

Treatment Coxsackie viruses are not affected by antibiotics Aspirin codeine or morphine is often required for symptomatic relief of pain The usual measures for relief of pleurisy (p 38) may be helpful

tum) is a rarer manifestation of primary infection which occurs in persons with eczema or neurodermatitis Large areas of abnormal skin are involved the grouped vesicles usually appearing in crops over a period of several days hence the similarity to varicella The fever may reach 106 F and marked prostration is not uncommon The fever subsides during the second week coincident with the crusting and healing of the skin lesions

Meningoencephalitis was formerly thought to be a rare form of primary herpes in man but complement fixation tests indicate that 5 to 7 per cent of cases of aseptic meningitis may be due to this virus It is accompanied by fever headache gastrointestinal symptoms and signs of meningeal irritation and encephalitis

In addition to the *syndromes* described above herpes simplex has been known to occur in segmental nerve distribution simulating herpes zoster The occurrence of repeated attacks in the same area is suggestive

Visceral disease characterized by fulminating generalized infection with fever viremia and necrotic lesions in the liver and other viscera and frequently terminating in death has been recently recognized as a clinical entity in newborn infants Skin lesions are not present in all infants Most cases have been in premature infants or when the mother was undergoing a primary herpetic infection herself In several cases the mother was known to have had repeated herpes vulvovaginitis and presumably the infant was infected in traversing the birth canal

Laboratory Findings The total leukocyte count is usually normal or only slightly increased with a normal differential index The diagnosis can be confirmed in the laboratory by (1) isolation and identification of the virus (2) demonstration of typical eosinophilic intranuclear inclusions in tissue sections or vesicle fluid or (3) in primary infections a rising titer of specific neutralizing antibodies The acute phase serum should be collected before the fifth day of illness as antibodies appear early In central nervous system infection the spinal fluid pressure and protein are slightly increased and a pleocytosis up to 500 cells is observed with many polymorphonuclear leukocytes early changing later to mononuclears

Differential Diagnosis The history and clinical appearance of the recurrent skin and eye manifestations are usually sufficient to establish the diagnosis

The laboratory tests enumerated above are confirmatory in doubtful cases and are essential for absolute diagnosis in the primary manifestations The condition is often confused with Vincent's angina or trench mouth which responds dramatically to parenteral penicillin Recurrent solitary aphthous ulcers in the mouth are not caused by herpes simplex

In herpangina caused by group A Coxsackie virus the vesicles are confined to the posterior part of the mouth and the disease occurs in epidemics Large bullae recurrent attacks and normal lymph nodes are seen in erythema multiforme

Eczema herpeticum may be easily confused with secondary bacterial infection of eczema Extensive weeping and crusting may obscure the grouped vesicular nature of the lesion before the crusts are removed by wet dressings Eczema vaccinatum (generalized vaccinia) usually presents larger vesicles with a central indentation but this characteristic is not constant Herpetic meningoencephalitis must be differentiated from bacterial and viral encephalitides particularly epidemic viral encephalitis poliomyelitis lymphocytic choriomeningitis and postinfectious encephalitis (see p 1071)

Treatment No specific treatment is available Repeated vaccination with calf lymph vaccinia virus is currently in vogue but the apparent successes can probably be explained by the supportive psychotherapy Laboratory studies reveal no cross protection or interference between these two viruses It is desirable to have the local treatment of eye lesions supervised by an ophthalmologist

Penicillin and other antibiotics may be helpful in controlling secondary bacterial infection In acute gingivostomatitis the maintenance of adequate hydration and nutrition are aided by the local application before meals of 1 per cent Pontocaine A detergent mouth wash such as 1 1 000 Zephiran helps to maintain oral hygiene and inhibit bacterial proliferation In eczema herpeticum and visceral disease supportive therapy fluid replacement blood transfusions and appropriate antibacterial measures are indicated Convalescent serum and gamma globulin have not been beneficial

Prognosis Except for complications following infection of the cornea recurrent herpes has high nuisance value but few sequelae The primary manifestations run a self limited course except for meningoencephalitis and visceral disease which are sometimes fatal and eczema herpeticum in which the mortality rate may be 20 per cent

chorioallantoic membrane of embryonated eggs or in tissue culture

Epidemiology The serums of most adults (70 to 90 per cent) contain neutralizing antibodies against herpes simplex many of these individuals experience recurrent manifestations of disease under suitable stimuli Fever whether due to infectious diseases or artificially induced (fever blister) and the common cold (cold sore") are probably the most frequent precipitants of recurrent herpes while emotional disturbance physical fatigue sunburn menstruation and food allergy are less common The virus remains latent in the tissues between attacks but is sufficiently active to stimulate antibody production Virus has frequently been found in the saliva when there was no clinical evidence of disease Adults who have never been infected may contract a primary infection if suitably exposed Full term newborn infants are immune by virtue of transplacental transfer of antibodies which they gradually lose after the first few months of life However by the fifth year the percentage of children with specific neutralizing antibodies approaches that observed in adults indicating a high infection rate during infancy The clinical syndromes recognized as primary infection in this age group account for only 15 per cent of serologic infections Herpes simplex has evolved an unusually successful host parasite relationship with man Most people harbor the virus from infancy to old age with little inconvenience to themselves and even the primary contact in infancy is usually not accompanied by manifest clinical disease

Pathogenesis It is probable that during latent periods the virus lives within the cells since the body fluids contain sufficient neutralizing antibody to inactivate the virus The various precipitating factors which induce recurrent disease may have a common denominator in altered physiology of the host cell which permits the virus to multiply but little specific information is available on this point Skin biopsies taken during the early vesicular stage show congestion of the dermis with swelling and ballooning degeneration of prickle cells of the epidermis In some of these the nuclear basichromatin is collected at the periphery and the entire central area of the enlarged nucleus is filled with a homogeneous mass which at first stains blue and later red with hematoxylin and eosin This is the type A inclusion body found wherever there is active herpes simplex infection Multinucleated giant cells with each nucleus containing an inclusion body are frequently seen in biopsies of infected human skin

The intraepidermal vesicle does not extend below the basement membrane and hence does not cause scarring although depigmentation may persist for some time in dark skinned people In the healing phase the vesicle and corium are densely infiltrated with inflammatory cells

Manifestations *Recurrent herpes simplex* is a circumscribed eruption consisting of closely grouped thin walled vesicles on an erythematous base which tends to recur repeatedly in the same area of the skin particularly at mucocutaneous junctions It begins as a mild itching or burning lesions appear which rapidly become papular and vesiculate and then pass successively through crusting scab formation and desiccation the whole process taking from 3 to 14 days It is typically not accompanied by fever regional lymphadenopathy or other signs of systemic illness The disease is self limited and is commonly identified with its anatomic location—herpes facialis labialis nasalis progenitalis or vulvovaginalis

Herpetic keratoconjunctivitis is characterized usually by swelling and congestion of the conjunctiva with superficial opacities in the cornea and a palpable preauricular lymph node Bacterial cultures are sterile hypesthesia is a prominent sign The presence of typical herpetic vesicles on the eyelids may aid in the diagnosis however the recurrent attacks are frequently confined to the cornea in the form of dendritic ulcers or less often as punctate marginate or disciform ulcers The corneal ulcerations may persist for several weeks and respond poorly to local therapy they are superficial but the occurrence of repeated attacks poses a threat to vision

Traumatic herpes designates those cases where the primary infection occurs at the site of a skin abrasion on the hand elbow finger or other skin area not commonly associated with the disease Repeated recurrences have been observed at the same site over a period of many years

Acute herpetic gingivostomatitis is the commonest form of primary infection and is seen most frequently in children from one to four years of age less often in adults It is characterized by gradual or sudden onset with fever malaise sore mouth and throat and extreme irritability sometimes alternating with lethargy The fever may reach 104 F but is usually 101 to 103 F Physical examination reveals multiple painful shallow aphthous ulcers on a red base scattered over the buccal mucous membranes tongue and oropharynx The gums are swollen bleed easily on manipulation and are typically most inflamed at the gingival margin The regional lymph nodes are large and tender Fever and pain usually persist for 6 to 8 days followed by gradual healing of the ulcers during the following week The ulcers may be confined to or appear first in the pharynx (herpetic pharyngitis) and in such cases the diagnosis is commonly missed

Eczema herpeticum (Kaposi s varicelliform erup

187 DENGUE
Robert R Wagner

Definition Dengue is an acute viral disease characterized by a diphasic course fever myalgia morbilliform rash transient personality changes and leukopenia

Epidemiology The infection is transmitted by *Aedes aegypti* and other species of *Aedes* mosquitoes which harbor the virus throughout their lives but do not pass it on to their offspring Man and monkeys constitute the only known reservoirs of infection Dengue is endemic in tropical and subtropical areas where mosquitoes survive throughout the year Summer epidemics have occurred in the United States particularly in port cities but the climate of this country is not favorable for the establishment of endemic foci The epidemiologic characteristics of dengue closely resemble those of yellow fever the two diseases also have a similar geographic distribution except in southeast Asia where dengue is prevalent but yellow fever is unknown

Etiology Large quantities of virus are present in the blood during the early phase of the disease but nothing is known of the pathogenesis or site of viral multiplication Virus isolated directly from man or mosquitoes is infectious for volunteers but is not pathogenic for laboratory animals and produces no inclusion bodies or other recognizable lesions During the Second World War Sabin and Schlesinger demonstrated that dengue virus produces fatal encephalitis in suckling and adult mice after repeated brain passages Mouse adapted virus has been cultivated in tissue cultures of monkey kidney epithelium All strains of dengue virus fall into two immunologic categories designated as Hawaiian (type 1) and New Guinea C (type 2) Both types are related antigenically to the viruses of yellow fever and Japanese B West Nile and St Louis encephalitis

Manifestations The incubation period is usually 5 to 9 days with a range of 3 to 15 days About half the cases have a sudden and dramatic onset with chills or chilly sensations profuse diaphoresis and temperature elevation of 102 to 106 F Prodromal symptoms of malaise anorexia and lethargy precede the fever in milder forms of the disease Severe frontal headache retroorbital pain and excruciating low backache are almost invariably present Dengue is popularly known as breakbone fever" because of incapacitating pains in the muscles and periarticular tissues of the extremities in more than half the cases The majority of patients experience nausea constipation and disturbances of taste and smell in the early phases diarrhea may be present late in the course Agitation and insomnia alternate with depression and fitful sleep A primary rash consisting of blotchy erythema or flushing of the face accompanies the initial temperature elevation in about a third of the patients Moderate conjunctival and pharyngeal reddening may also be noted The symptoms persist for 3 or 4 days following which the temperature falls by crisis or rapid lysis A bright red morbilliform or punctate rash appears in three fourths of the patients on the third to sixth day of illness the eruption starts on the dorsal surfaces of the hands and feet and rapidly extends over the trunk and face Generalized lymph node enlargement is commonly encountered but the spleen is rarely palpable

Many patients develop a *secondary rise in temperature* 12 to 72 hr after subsidence of the initial episode producing the typical saddleback fever curve of dengue All the symptoms return with increased intensity delirium and depression may be particularly marked Cold mottled extremities hypotension bradycardia and a dicrotic pulse may be noted during the second phase of the disease The total duration of acute illness is usually 6 to 9 days but convalescence is often prolonged for several weeks by marked weakness apathy radicular pains aching legs and back and marked personality changes A rare disturbance is transient loss of pupillary accommodation owing to paralysis of the ciliary muscle of the eye

The incidence of *complications* varies in different epidemics Bleeding tendencies are occasionally noted as manifested by purpura petechial rashes epistaxes and hemorrhages from the intestine and vagina Jaundice occurs in less than 1 case in 100 Herpes labialis otitis media and bronchopneumonia are uncommon complications The mortality rate is consistently low

Laboratory Findings Complement fixing and neutralizing antibodies appear in the serum after the seventh day of disease Leukopenia of 2 000 to 5 000 cells per cubic millimeter and toxic granulation of the polymorphonuclear leukocytes are constant features of the early phase of the disease Moderate leukocytosis often occurs during convalescence Oliguria and proteinuria are common with high fever

Differential Diagnosis The sudden onset of chilliness fever and myalgia may simulate influenza malaria sandfly fever and leptospirosis but rash is uncommon in these diseases Exanthematous viral infections such as measles can usually be differentiated by their clinical course and epidemiology

Treatment No specific treatment is available but analgesics and sedatives afford symptomatic relief of pain and anxiety Control of mosquitoes by sanitation and insecticides decreases the incidence of dengue in endemic areas Dengue virus cultivated in mouse brain has been used as a living attenuated vaccine unfortunately it causes mild dengue

186 PHLEBOTOMUS FEVER
W Elizabeth Gambrell

Definition Phlebotomus fever often referred to as *sandfly pappataci* or *3 day fever* is a benign self limited viral infection characterized by fever severe headache conjunctivitis general malaise and leukopenia It is transmitted by the sandfly *Phlebotomus papatasii*

Etiology The virus has been isolated by passing infectious human serum through gradocol membranes Its size is estimated at between 40 and 60 mμ In frozen or lyophilized states the virus has been preserved for many years In 1952 one strain of the virus from serum stored in the frozen state for 9 years was adapted to brains of newborn mice Several strains have been isolated and appear to be immunologically different as evidenced by lack of cross immunity in inoculated volunteers

Epidemiology The disease is endemic in tropical and subtropical countries particularly in those parts of Europe Africa and Asia between 20 and 45 north latitude where the vector *P papatasii* propagates In native populations it occurs during infancy and childhood as a mild febrile illness and is usually not recognized as a distinct clinical entity Outbreaks among military personnel and other immigrants who move into endemic areas occur with disturbing severity Patients are infectious for the sandfly 1 day before the onset of fever and 2 days after the onset The reservoir of the virus during the winter is not known

Manifestations After an incubation period of from 2 to 6 days there is sudden onset of malaise giddiness pains in the back and extremities severe headache (usually frontal) and pain in the eyes Fever is always present and lasts from 2 to 4 days The temperature may rise to 104 5 F usually within the first 24 hr then gradually subsides The pulse rate is fast at first but returns to normal more rapidly than the temperature and a bradycardia often occurs during convalescence An erythema occurs on the face and exposed parts of the neck and chest but no true rash develops The conjunctivas are injected and the eyeballs are tender Convalescence is characterized by prostration and occasionally by marked mental depression

Laboratory Findings A leukopenia with a predominance of neutrophilic leukocytes many of which are immature is present and there is a decrease in lymphocytes The greatest drop in the leukocyte count occurs at the end of the febrile period The urine is normal and there is no laboratory evidence of liver damage

Differential Diagnosis The diagnosis usually is made on clinical and epidemiologic grounds and is suggested by the occurrence of fever of short duration during the hot dry season in countries known to harbor the vector Phlebotomus fever is sometimes confused with dengue influenza infectious hepatitis and malaria It differs from dengue in the short duration of the fever and the absence of rash and lymphadenopathy from influenza by its seasonal incidence and the absence of catarrhal symptoms from infectious hepatitis by the absence of jaundice and by normal liver function tests Cases are often misdiagnosed as malaria but no chills occur and blood films are negative for parasites

Treatment No specific therapy is known Control measures consist of eradicating the vector within 100 to 200 m of living quarters DDT residual spray is successful in killing *P papatasii* at its breeding site and within habitations

been observed Generalized skin eruptions and arthritis have also been described these apparently have been provoked occasionally by the performance of skin tests for the disease

Many years after the onset of the infection the patient may develop a proctitis associated with rectal bleeding and a purulent discharge Eventually there is scar formation and a complete fibrous ring may develop producing a *rectal stricture* which may necessitate colostomy Rectal lesions are found predominantly in women and are the result of the lymphatic drainage from the posterior part of the vulva and the vagina into the perirectal and retroperitoneal lymph nodes In the male the lymph vessels drain from the penis to the inguinal area and thence to the deep iliac nodes Rectal involvement in the male is often due to direct infection of the anorectal area

Another late complication of lymphogranuloma venereum is elephantiasis of the external genitalia This is known as *esthiomene* and is caused by interference with lymphatic drainage Ulceration is frequent and secondary infection may cause marked destruction of the genitalia

Diagnosis Isolation of the virus is the most accurate means of diagnosis but it is too laborious for general use The diagnosis is usually based upon the clinical findings together with a positive intradermal test and complement fixation reaction Commercial antigens are available for these A positive skin (Frei) test is of limited value as it merely indicates that the patient has been infected with the virus at some previous time In a recently acquired infection the complement fixation test will usually be positive in a high titer (1 80 to 1 640) Furthermore a change in the titer of circulating antibodies may be found in successive tests Biopsy of the primary lesion or of a lymph node should be done whenever feasible since the histologic picture is sufficiently characteristic to permit a diagnosis and to differentiate this disease from other venereal infections

Treatment Sulfonamide therapy has been the standard treatment of the early manifestations of lymphogranuloma venereum Sulfadiazine in doses of 4 Gm a day usually results in disappearance of symptoms and lesions within 1 to 2 weeks Chloramphenicol and the tetracyclines have been found to be of some value in the treatment of buboes draining sinuses and early proctitis These antibiotics do not seem to be more effective than the sulfonamides There is evidence to suggest that sulfonamide therapy may not destroy the virus completely and that it may persist in the body after the acute infection has subsided The late manifestations of the disease such as rectal stricture and elephantiasis do not usually respond to any form of medication and treatment is chiefly surgical Buboes which have become fluctuant should be aspirated to prevent spontaneous rupture and subsequent sinus formation

189 COLORADO TICK FEVER

Edward S Miller

Definition Colorado tick fever is an acute infectious illness with a characteristic intermittent fever It is caused by a filtrable virus and transmitted to man by the bite of an infected tick

Etiology The causative agent is a small virus (35 to 50 mμ) It is unusually hardy and can be recovered from specimens of human blood which have been shipped unrefrigerated via ordinary mail routes The virus produces a fatal disease in suckling mice and hamsters it can be adapted to the adult mouse and to the chick embryo This is the only tick transmitted virus disease of man found in the Western Hemisphere

Epidemiology All cases so far reported have originated in the western part of the United States Colorado Wyoming Oregon Utah Idaho California Montana, Nevada and Washington Since many tourists visit these states during the tick season and since Colorado tick fever is a decidedly common affliction it is incumbent on North American physicians to be aware of this disease Affected persons usually give a history of having been in a tick infested area 3 to 6 days prior to the onset of symptoms In many instances patients can recall having found ticks on themselves however the
